                .Select(AsBookDto);
        }

        [Route("~/api/authors/{authorId}/books")]
        public IQueryable<BookDto> GetBooksByAuthor(int authorId)
        {
            return db.Books.Include(b => b.Author)
                .Where(b => b.AuthorId == authorId)
                .Select(AsBookDto);
        }

        [Route("date/{pubdate:datetime:regex(\\d{4}-\\d{2}-\\d{2})}")]
        [Route("date/{*pubdate:datetime:regex(\\d{4}/\\d{2}/\\d{2})}")]
        public IQueryable<BookDto> GetBooks(DateTime pubdate)
        {
            return db.Books.Include(b => b.Author)
                .Where(b => DbFunctions.TruncateTime(b.PublishDate)
```

```
                .Where(b => DbFunctions.TruncateTime(b.PublishDate)
                    == DbFunctions.TruncateTime(pubdate))
                .Select(AsBookDto);
        }

        protected override void Dispose(bool disposing)
        {
            db.Dispose();
            base.Dispose(disposing);
        }
    }
}
```

Summary

Attribute routing gives you more control and greater flexibility when designing the URIs for your API.

Working with Data in ASP.NET Web API

2/20/2020 • 2 minutes to read • Edit Online

How to program CRUD (create, read, update, delete) operations in Web API.

- Using Web API 2 with Entity Framework 6
  - Create the Project
  - Add Models and Controllers
  - Seed the Database
  - Handling Entity Relations
  - Create Data Transfer Objects (DTOs)
  - Create the JavaScript Client
  - Create the View (UI)
  - Display Item Details
  - Add a New Item to the Database
  - Publish the App to Azure Websites

Using Web API 2 with Entity Framework 6

Using Web API 2 with Entity Framework 6

2/20/2020 • 2 minutes to read • Edit Online

Download Completed Project

This tutorial teaches you the basics of creating a web application with an ASP.NET Web API back end. The tutorial uses Entity Framework 6 for the data layer, and Knockout.js for the client-side JavaScript application. The tutorial also shows how to deploy the app to Azure App Service Web Apps.

Software versions used in the tutorial

- Web API 2.1
- Visual Studio 2017 (download Visual Studio 2017 here)
- Entity Framework 6
- .NET 4.7
- Knockout.js 3.1

This tutorial uses ASP.NET Web API 2 with Entity Framework 6 to create a web application that manipulates a back-end database. Here is a screen shot of the application that you will create.

The app uses a single-page application (SPA) design. "Single-page application" is the general term for a web application that loads a single HTML page and then updates the page dynamically, instead of loading new pages. After the initial page load, the app talks with the server through AJAX requests. The AJAX requests return JSON data, which the app uses to update the UI.

AJAX isn't new, but today there are JavaScript frameworks that make it easier to build and maintain a large sophisticated SPA application. This tutorial uses Knockout.js, but you can use any JavaScript client framework.

Here are the main building blocks for this app:

- ASP.NET MVC creates the HTML page.

- ASP.NET Web API handles the AJAX requests and returns JSON data.
- Knockout.js data-binds the HTML elements to the JSON data.
- Entity Framework talks to the database.

See this app running on Azure

Would you like to see the finished site running as a live web app? You can deploy a complete version of the app to your Azure account by selecting the following button.

Deploy to Azure

You need an Azure account to deploy this solution to Azure. If you do not already have an account, you have the following options:

- Open an Azure account for free - You get credits you can use to try out paid Azure services, and even after they're used up you can keep the account and use free Azure services.
- Activate MSDN subscriber benefits - Your MSDN subscription gives you credits every month that you can use for paid Azure services.

Create the project

Open Visual Studio. From the **File** menu, select **New**, then select **Project**. (Or select **New Project** on the Start page.)

In the **New Project** dialog, select **Web** in the left pane and **ASP.NET Web Application (.NET Framework)** in the middle pane. Name the project **BookService** and select **OK**.

In the **New ASP.NET Project** dialog, select the **Web API** template.

Select **OK** to create the project.

Configure Azure settings (optional)

After you create the project, you can choose to deploy to Azure App Service Web Apps at any time.

1. In Solution Explorer, right-click on your project and select **Publish**.
2. In the window that appears, select **Start**. The **Pick a publish target** dialog box appears.

3. Select **Create Profile**. The **Create App Service** dialog box appears.

Accept the defaults, or enter different values for the application name, resource group, hosting plan, Azure subscription, and geographical region.

4. Select **Create a SQL database**. The **Configure SQL Server** dialog box appears.

Accept the defaults or enter different values. Enter an **Administrator Username** and **Administrator Password** for your new database. Select **OK** when you're done. The **Create App Service** page reappears.

5. Select **Create** to create your profile. A message appears in the lower-right corner indicating that deployment is in progress. After a short while, the **Publish** window reappears.

The profile you created to deploy the app is now available.

Add Models and Controllers

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

In this section, you will add model classes that define the database entities. Then you will add Web API controllers that perform CRUD operations on those entities.

Add Model Classes

In this tutorial, we'll create the database by using the "Code First" approach to Entity Framework (EF). With Code First, you write C# classes that correspond to database tables, and EF creates the database. (For more information, see Entity Framework Development Approaches.)

We start by defining our domain objects as POCOs (plain-old CLR objects). We will create the following POCOs:

- Author
- Book

In Solution Explorer, right click the Models folder. Select **Add**, then select **Class**. Name the class `Author`.

Replace all of the boilerplate code in Author.cs with the following code.

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace BookService.Models
{
    public class Author
    {
        public int Id { get; set; }
        [Required]
        public string Name { get; set; }
    }
}
```

Add another class named `Book`, with the following code.

```
using System.ComponentModel.DataAnnotations;

namespace BookService.Models
{
    public class Book
    {
        public int Id { get; set; }
        [Required]
        public string Title { get; set; }
        public int Year { get; set; }
        public decimal Price { get; set; }
        public string Genre { get; set; }

        // Foreign Key
        public int AuthorId { get; set; }
        // Navigation property
        public Author Author { get; set; }
    }
}
```

Entity Framework will use these models to create database tables. For each model, the `Id` property will become the primary key column of the database table.

In the Book class, the `AuthorId` defines a foreign key into the `Author` table. (For simplicity, I'm assuming that each book has a single author.) The book class also contains a navigation property to the related `Author`. You can use the navigation property to access the related `Author` in code. I say more about navigation properties in part 4, Handling Entity Relations.

Add Web API Controllers

In this section, we'll add Web API controllers that support CRUD operations (create, read, update, and delete). The controllers will use Entity Framework to communicate with the database layer.

First, you can delete the file Controllers/ValuesController.cs. This file contains an example Web API controller, but you don't need it for this tutorial.

Next, build the project. The Web API scaffolding uses reflection to find the model classes, so it needs the compiled assembly.

In Solution Explorer, right-click the Controllers folder. Select **Add**, then select **Controller**.

In the **Add Scaffold** dialog, select "Web API 2 Controller with actions, using Entity Framework". Click **Add**.

In the **Add Controller** dialog, do the following:

1. In the **Model class** dropdown, select the `Author` class. (If you don't see it listed in the dropdown, make sure that you built the project.)
2. Check "Use async controller actions".
3. Leave the controller name as "AuthorsController".
4. Click plus (+) button next to **Data Context Class**.

In the **New Data Context** dialog, leave the default name and click **Add**.

Click **Add** to complete the **Add Controller** dialog. The dialog adds two classes to your project:

- `AuthorsController` defines a Web API controller. The controller implements the REST API that clients use to perform CRUD operations on the list of authors.
- `BookServiceContext` manages entity objects during run time, which includes populating objects with data from a database, change tracking, and persisting data to the database. It inherits from `DbContext`.

At this point, build the project again. Now go through the same steps to add an API controller for `Book` entities. This time, select `Book` for the model class, and select the existing `BookServiceContext` class for the data context class. (Don't create a new data context.) Click **Add** to add the controller.

Use Code First Migrations to Seed the Database

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

In this section, you will use Code First Migrations in EF to seed the database with test data.

From the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Enable-Migrations
```

This command adds a folder named Migrations to your project, plus a code file named Configuration.cs in the Migrations folder.

Open the Configuration.cs file. Add the following **using** statement.

```
using BookService.Models;
```

Then add the following code to the **Configuration.Seed** method:

```
protected override void Seed(BookService.Models.BookServiceContext context)
{
    context.Authors.AddOrUpdate(x => x.Id,
        new Author() { Id = 1, Name = "Jane Austen" },
        new Author() { Id = 2, Name = "Charles Dickens" },
        new Author() { Id = 3, Name = "Miguel de Cervantes" }
        );

    context.Books.AddOrUpdate(x => x.Id,
        new Book() { Id = 1, Title = "Pride and Prejudice", Year = 1813, AuthorId = 1,
            Price = 9.99M, Genre = "Comedy of manners" },
        new Book() { Id = 2, Title = "Northanger Abbey", Year = 1817, AuthorId = 1,
            Price = 12.95M, Genre = "Gothic parody" },
        new Book() { Id = 3, Title = "David Copperfield", Year = 1850, AuthorId = 2,
            Price = 15, Genre = "Bildungsroman" },
        new Book() { Id = 4, Title = "Don Quixote", Year = 1617, AuthorId = 3,
            Price = 8.95M, Genre = "Picaresque" }
        );
}
```

In the Package Manager Console window, type the following commands:

```
Add-Migration Initial
Update-Database
```

The first command generates code that creates the database, and the second command executes that code. The database is created locally, using LocalDB.

Explore the API (Optional)

Press F5 to run the application in debug mode. Visual Studio starts IIS Express and runs your web app. Visual Studio then launches a browser and opens the app's home page.

When Visual Studio runs a web project, it assigns a port number. In the image below, the port number is 50524. When you run the application, you'll see a different port number.

The home page is implemented using ASP.NET MVC. At the top of the page, there is a link that says "API". This link brings you to an auto-generated help page for the web API. (To learn how this help page is generated, and how you can add your own documentation to the page, see Creating Help Pages for ASP.NET Web API.) You can click on the help page links to see details about the API, including the request and response format.

The API enables CRUD operations on the database. The following summarizes the API.

AUTHORS	
GET api/authors	Get all authors.
GET api/authors/{id}	Get an author by ID.

AUTHORS	
POST /api/authors	Create a new author.
PUT /api/authors/{id}	Update an existing author.
DELETE /api/authors/{id}	Delete an author.

BOOKS	
GET /api/books	Get all books.
GET /api/books/{id}	Get a book by ID.
POST /api/books	Create a new book.
PUT /api/books/{id}	Update an existing book.
DELETE /api/books/{id}	Delete a book.

View the Database (Optional)

When you ran the Update-Database command, EF created the database and called the `Seed` method. When you run the application locally, EF uses LocalDB. You can view the database in Visual Studio. From the **View** menu, select **SQL Server Object Explorer**.

In the **Connect to Server** dialog, in the **Server Name** edit box, type "(localdb)\v11.0". Leave the **Authentication** option as "Windows Authentication". Click **Connect**.

Visual Studio connects to LocalDB and shows your existing databases in the SQL Server Object Explorer window. You can expand the nodes to see the tables that EF created.

To view the data, right-click a table and select **View Data**.

The following screenshot shows the results for the Books table. Notice that EF populated the database with the seed data, and the table contains the foreign key to the Authors table.

SQLQuery1.sql | dbo.Books [Data]

Max Rows: 1000

BookId	Title	Year	AuthorId
1	Pride and Pr...	1813	1
2	Emma	1815	1
3	David Copp...	1850	2
4	Don Quixote	1617	3
NULL	NULL	NULL	NULL

Handling Entity Relations

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

This section describes some details of how EF loads related entities, and how to handle circular navigation properties in your model classes. (This section provides background knowledge, and is not required to complete the tutorial. If you prefer, skip to Part 5..)

Eager Loading versus Lazy Loading

When using EF with a relational database, it's important to understand how EF loads related data.

It's also useful to see the SQL queries that EF generates. To trace the SQL, add the following line of code to the `BookServiceContext` constructor:

```
public BookServiceContext() : base("name=BookServiceContext")
{
    // New code:
    this.Database.Log = s => System.Diagnostics.Debug.WriteLine(s);
}
```

If you send a GET request to /api/books, it returns JSON like the following:

```
[
  {
    "BookId": 1,
    "Title": "Pride and Prejudice",
    "Year": 1813,
    "Price": 9.99,
    "Genre": "Comedy of manners",
    "AuthorId": 1,
    "Author": null
  },
  ...
```

You can see that the Author property is null, even though the book contains a valid AuthorId. That's because EF is not loading the related Author entities. The trace log of the SQL query confirms this:

```
SELECT
    [Extent1].[BookId] AS [BookId],
    [Extent1].[Title] AS [Title],
    [Extent1].[Year] AS [Year],
    [Extent1].[Price] AS [Price],
    [Extent1].[Genre] AS [Genre],
    [Extent1].[AuthorId] AS [AuthorId]
    FROM [dbo].[Books] AS [Extent1]
```

The SELECT statement takes from the Books table, and does not reference the Author table.

For reference, here is the method in the `BooksController` class that returns the list of books.

```
public IQueryable<Book> GetBooks()
{
    return db.Books;
}
```

Let's see how we can return the Author as part of the JSON data. There are three ways to load related data in Entity Framework: eager loading, lazy loading, and explicit loading. There are trade-offs with each technique, so it's important to understand how they work.

Eager Loading

With *eager loading*, EF loads related entities as part of the initial database query. To perform eager loading, use the **System.Data.Entity.Include** extension method.

```
public IQueryable<Book> GetBooks()
{
    return db.Books
        // new code:
        .Include(b => b.Author);
}
```

This tells EF to include the Author data in the query. If you make this change and run the app, now the JSON data looks like this:

```
[
  {
    "BookId": 1,
    "Title": "Pride and Prejudice",
    "Year": 1813,
    "Price": 9.99,
    "Genre": "Comedy of manners",
    "AuthorId": 1,
    "Author": {
      "AuthorId": 1,
      "Name": "Jane Austen"
    }
  },
  ...
```

The trace log shows that EF performed a join on the Book and Author tables.

```
SELECT
    [Extent1].[BookId] AS [BookId],
    [Extent1].[Title] AS [Title],
    [Extent1].[Year] AS [Year],
    [Extent1].[Price] AS [Price],
    [Extent1].[Genre] AS [Genre],
    [Extent1].[AuthorId] AS [AuthorId],
    [Extent2].[AuthorId] AS [AuthorId1],
    [Extent2].[Name] AS [Name]
    FROM  [dbo].[Books] AS [Extent1]
    INNER JOIN [dbo].[Authors] AS [Extent2] ON [Extent1].[AuthorId] = [Extent2].[AuthorId]
```

Lazy Loading

With lazy loading, EF automatically loads a related entity when the navigation property for that entity is dereferenced. To enable lazy loading, make the navigation property virtual. For example, in the Book class:

```
public class Book
{
    // (Other properties)

    // Virtual navigation property
    public virtual Author Author { get; set; }
}
```

Now consider the following code:

```
var books = db.Books.ToList();  // Does not load authors
var author = books[0].Author;   // Loads the author for books[0]
```

When lazy loading is enabled, accessing the `Author` property on `books[0]` causes EF to query the database for the author.

Lazy loading requires multiple database trips, because EF sends a query each time it retrieves a related entity. Generally, you want lazy loading disabled for objects that you serialize. The serializer has to read all of the properties on the model, which triggers loading the related entities. For example, here are the SQL queries when EF serializes the list of books with lazy loading enabled. You can see that EF makes three separate queries for the three authors.

```
SELECT
    [Extent1].[BookId] AS [BookId],
    [Extent1].[Title] AS [Title],
    [Extent1].[Year] AS [Year],
    [Extent1].[Price] AS [Price],
    [Extent1].[Genre] AS [Genre],
    [Extent1].[AuthorId] AS [AuthorId]
    FROM [dbo].[Books] AS [Extent1]

SELECT
    [Extent1].[AuthorId] AS [AuthorId],
    [Extent1].[Name] AS [Name]
    FROM [dbo].[Authors] AS [Extent1]
    WHERE [Extent1].[AuthorId] = @EntityKeyValue1

SELECT
    [Extent1].[AuthorId] AS [AuthorId],
    [Extent1].[Name] AS [Name]
    FROM [dbo].[Authors] AS [Extent1]
    WHERE [Extent1].[AuthorId] = @EntityKeyValue1

SELECT
    [Extent1].[AuthorId] AS [AuthorId],
    [Extent1].[Name] AS [Name]
    FROM [dbo].[Authors] AS [Extent1]
    WHERE [Extent1].[AuthorId] = @EntityKeyValue1
```

There are still times when you might want to use lazy loading. Eager loading can cause EF to generate a very complex join. Or you might need related entities for a small subset of the data, and lazy loading would be more efficient.

One way to avoid serialization problems is to serialize data transfer objects (DTOs) instead of entity objects. I'll show this approach later in the article.

Explicit Loading

Explicit loading is similar to lazy loading, except that you explicitly get the related data in code; it doesn't happen automatically when you access a navigation property. Explicit loading gives you more control over when to load

related data, but requires extra code. For more information about explicit loading, see Loading Related Entities.

Navigation Properties and Circular References

When I defined the Book and Author models, I defined a navigation property on the `Book` class for the Book-Author relationship, but I did not define a navigation property in the other direction.

What happens if you add the corresponding navigation property to the `Author` class?

```
public class Author
{
    public int AuthorId { get; set; }
    [Required]
    public string Name { get; set; }

    public ICollection<Book> Books { get; set; }
}
```

Unfortunately, this creates a problem when you serialize the models. If you load the related data, it creates a circular object graph.

When the JSON or XML formatter tries to serialize the graph, it will throw an exception. The two formatters throw different exception messages. Here is an example for the JSON formatter:

```
{
  "Message": "An error has occurred.",
  "ExceptionMessage": "The 'ObjectContent`1' type failed to serialize the response body for content type
      'application/json; charset=utf-8'.",
  "ExceptionType": "System.InvalidOperationException",
  "StackTrace": null,
  "InnerException": {
    "Message": "An error has occurred.",
    "ExceptionMessage": "Self referencing loop detected with type 'BookService.Models.Book'.
        Path '[0].Author.Books'.",
    "ExceptionType": "Newtonsoft.Json.JsonSerializationException",
    "StackTrace": "..."
     }
}
```

Here is the XML formatter:

```
<Error>
  <Message>An error has occurred.</Message>
  <ExceptionMessage>The 'ObjectContent`1' type failed to serialize the response body for content type
    'application/xml; charset=utf-8'.</ExceptionMessage>
  <ExceptionType>System.InvalidOperationException</ExceptionType>
  <StackTrace />
  <InnerException>
    <Message>An error has occurred.</Message>
    <ExceptionMessage>Object graph for type 'BookService.Models.Author' contains cycles and cannot be
      serialized if reference tracking is disabled.</ExceptionMessage>
    <ExceptionType>System.Runtime.Serialization.SerializationException</ExceptionType>
    <StackTrace> ... </StackTrace>
  </InnerException>
</Error>
```

One solution is to use DTOs, which I describe in the next section. Alternatively, you can configure the JSON and XML formatters to handle graph cycles. For more information, see Handling Circular Object References.

For this tutorial, you don't need the `Author.Book` navigation property, so you can leave it out.

Create Data Transfer Objects (DTOs)

2/20/2020 • 2 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

Right now, our web API exposes the database entities to the client. The client receives data that maps directly to your database tables. However, that's not always a good idea. Sometimes you want to change the shape of the data that you send to client. For example, you might want to:

- Remove circular references (see previous section).
- Hide particular properties that clients are not supposed to view.
- Omit some properties in order to reduce payload size.
- Flatten object graphs that contain nested objects, to make them more convenient for clients.
- Avoid "over-posting" vulnerabilities. (See Model Validation for a discussion of over-posting.)
- Decouple your service layer from your database layer.

To accomplish this, you can define a *data transfer object* (DTO). A DTO is an object that defines how the data will be sent over the network. Let's see how that works with the Book entity. In the Models folder, add two DTO classes:

```
namespace BookService.Models
{
    public class BookDto
    {
        public int Id { get; set; }
        public string Title { get; set; }
        public string AuthorName { get; set; }
    }
}

namespace BookService.Models
{
    public class BookDetailDto
    {
        public int Id { get; set; }
        public string Title { get; set; }
        public int Year { get; set; }
        public decimal Price { get; set; }
        public string AuthorName { get; set; }
        public string Genre { get; set; }
    }
}
```

The `BookDetailDto` class includes all of the properties from the Book model, except that `AuthorName` is a string that will hold the author name. The `BookDto` class contains a subset of properties from `BookDetailDto`.

Next, replace the two GET methods in the `BooksController` class, with versions that return DTOs. We'll use the LINQ **Select** statement to convert from Book entities into DTOs.

```
// GET api/Books
public IQueryable<BookDto> GetBooks()
{
    var books = from b in db.Books
                select new BookDto()
                {
                    Id = b.Id,
                    Title = b.Title,
                    AuthorName = b.Author.Name
                };

    return books;
}

// GET api/Books/5
[ResponseType(typeof(BookDetailDto))]
public async Task<IHttpActionResult> GetBook(int id)
{
    var book = await db.Books.Include(b => b.Author).Select(b =>
        new BookDetailDto()
        {
            Id = b.Id,
            Title = b.Title,
            Year = b.Year,
            Price = b.Price,
            AuthorName = b.Author.Name,
            Genre = b.Genre
        }).SingleOrDefaultAsync(b => b.Id == id);
    if (book == null)
    {
        return NotFound();
    }

    return Ok(book);
}
```

Here is the SQL generated by the new `GetBooks` method. You can see that EF translates the LINQ **Select** into a SQL SELECT statement.

```
SELECT
    [Extent1].[Id] AS [Id],
    [Extent1].[Title] AS [Title],
    [Extent2].[Name] AS [Name]
    FROM  [dbo].[Books] AS [Extent1]
    INNER JOIN [dbo].[Authors] AS [Extent2] ON [Extent1].[AuthorId] = [Extent2].[Id]
```

Finally, modify the `PostBook` method to return a DTO.

```
[ResponseType(typeof(BookDto))]
public async Task<IHttpActionResult> PostBook(Book book)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    db.Books.Add(book);
    await db.SaveChangesAsync();

    // New code:
    // Load author name
    db.Entry(book).Reference(x => x.Author).Load();

    var dto = new BookDto()
    {
        Id = book.Id,
        Title = book.Title,
        AuthorName = book.Author.Name
    };

    return CreatedAtRoute("DefaultApi", new { id = book.Id }, dto);
}
```

NOTE

In this tutorial, we're converting to DTOs manually in code. Another option is to use a library like AutoMapper that handles the conversion automatically.

Create the JavaScript Client

2/20/2020 • 2 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

In this section, you will create the client for the application, using HTML, JavaScript, and the Knockout.js library. We'll build the client app in stages:

- Showing a list of books.
- Showing a book detail.
- Adding a new book.

The Knockout library uses the Model-View-ViewModel (MVVM) pattern:

- The **model** is the server-side representation of the data in the business domain (in our case, books and authors).
- The **view** is the presentation layer (HTML).
- The **view model** is a JavaScript object that holds the models. The view model is a code abstraction of the UI. It has no knowledge of the HTML representation. Instead, it represents abstract features of the view, such as "a list of books".

The view is data-bound to the view model. Updates to the view model are automatically reflected in the view. The view model also gets events from the view, such as button clicks.

This approach makes it easy to change the layout and UI of your app, because you can change the bindings, without rewriting any code. For example, you might show a list of items as a `<ul>`, then change it later to a table.

Add the Knockout Library

In Visual Studio, from the **Tools** menu, select **NuGet Package Manager**. Then select **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Install-Package knockoutjs
```

This command adds the Knockout files to the Scripts folder.

Create the View Model

Add a JavaScript file named app.js to the Scripts folder. (In Solution Explorer, right-click the Scripts folder, select **Add**, then select **JavaScript File**.) Paste in the following code:

```
var ViewModel = function () {
    var self = this;
    self.books = ko.observableArray();
    self.error = ko.observable();

    var booksUri = '/api/books/';

    function ajaxHelper(uri, method, data) {
        self.error(''); // Clear error message
        return $.ajax({
            type: method,
            url: uri,
            dataType: 'json',
            contentType: 'application/json',
            data: data ? JSON.stringify(data) : null
        }).fail(function (jqXHR, textStatus, errorThrown) {
            self.error(errorThrown);
        });
    }

    function getAllBooks() {
        ajaxHelper(booksUri, 'GET').done(function (data) {
            self.books(data);
        });
    }

    // Fetch the initial data.
    getAllBooks();
};

ko.applyBindings(new ViewModel());
```

In Knockout, the `observable` class enables data-binding. When the contents of an observable change, the observable notifies all of the data-bound controls, so they can update themselves. (The `observableArray` class is the array version of *observable*.) To start with, our view model has two observables:

- `books` holds the list of books.
- `error` contains an error message if an AJAX call fails.

The `getAllBooks` method makes an AJAX call to get the list of books. Then it pushes the result onto the `books` array.

The `ko.applyBindings` method is part of the Knockout library. It takes the view model as a parameter and sets up the data binding.

Add a Script Bundle

Bundling is a feature in ASP.NET 4.5 that makes it easy to combine or bundle multiple files into a single file. Bundling reduces the number of requests to the server, which can improve page load time.

Open the file App_Start/BundleConfig.cs. Add the following code to the RegisterBundles method.

```
public static void RegisterBundles(BundleCollection bundles)
{
    // ...

    // New code:
    bundles.Add(new ScriptBundle("~/bundles/app").Include(
              "~/Scripts/knockout-{version}.js",
              "~/Scripts/app.js"));
}
```

PREVIOUS NEXT

Create the View (UI)

2/20/2020 • 2 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

In this section, you will start to define the HTML for the app, and add data binding between the HTML and the view model.

Open the file Views/Home/Index.cshtml. Replace the entire contents of that file with the following.

```
@section scripts {
  @Scripts.Render("~/bundles/app")
}

<div class="page-header">
  <h1>BookService</h1>
</div>

<div class="row">

  <div class="col-md-4">
    <div class="panel panel-default">
      <div class="panel-heading">
        <h2 class="panel-title">Books</h2>
      </div>
      <div class="panel-body">
        <ul class="list-unstyled" data-bind="foreach: books">
          <li>
            <strong><span data-bind="text: AuthorName"></span></strong>: <span data-bind="text: Title">
</span>
            <small><a href="#">Details</a></small>
          </li>
        </ul>
      </div>
    </div>
    <div class="alert alert-danger" data-bind="visible: error"><p data-bind="text: error"></p></div>
  </div>

  <div class="col-md-4">
    <!-- TODO: Book details -->
  </div>

  <div class="col-md-4">
    <!-- TODO: Add new book -->
  </div>
</div>
```

Most of the `div` elements are there for Bootstrap styling. The important elements are the ones with `data-bind` attributes. This attribute links the HTML to the view model.

For example:

```
<p data-bind="text: error">
```

In this example, the "`text`" binding causes the `<p>` element to show the value of the `error` property from the view model. Recall that `error` was declared as a `ko.observable`:

```
self.error = ko.observable();
```

Whenever a new value is assigned to `error`, Knockout updates the text in the `<p>` element.

The `foreach` binding tells Knockout to loop through the contents of the `books` array. For each item in the array, Knockout creates a new <li> element. Bindings inside the context of the `foreach` refer to properties on the array item. For example:

```
<span data-bind="text: Author"></span>
```

Here the `text` binding reads the Author property of each book.

If you run the application now, it should look like this:

The list of books loads asynchronously, after the page loads. Right now, the "Details" links are not functional. We'll add this functionality in the next section.

Display Item Details

2/20/2020 • 2 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

In this section, you will add the ability to view details for each book. In app.js, add to the following code to the view model:

```
self.detail = ko.observable();

self.getBookDetail = function (item) {
    ajaxHelper(booksUri + item.Id, 'GET').done(function (data) {
        self.detail(data);
    });
}
```

In Views/Home/Index.cshtml, add a data-bind element to the Details link:

```
<ul class="list-unstyled" data-bind="foreach: books">
  <li>
    <strong><span data-bind="text: AuthorName"></span></strong>: <span data-bind="text: Title"></span>
    <!-- New code -->
    <small><a href="#" data-bind="click: $parent.getBookDetail">Details</a></small>
  </li>
</ul>
```

This binds the click handler for the <a> element to the `getBookDetail` function on the view model.

In the same file, replace the following mark-up:

```
<div class="col-md-4">
    <!-- TODO: Book details -->
</div>
```

with this:

```
<!-- ko if:detail() -->

<div class="col-md-4">
<div class="panel panel-default">
  <div class="panel-heading">
    <h2 class="panel-title">Detail</h2>
  </div>
  <table class="table">
    <tr><td>Author</td><td data-bind="text: detail().AuthorName"></td></tr>
    <tr><td>Title</td><td data-bind="text: detail().Title"></td></tr>
    <tr><td>Year</td><td data-bind="text: detail().Year"></td></tr>
    <tr><td>Genre</td><td data-bind="text: detail().Genre"></td></tr>
    <tr><td>Price</td><td data-bind="text: detail().Price"></td></tr>
  </table>
</div>
</div>

<!-- /ko -->
```

This markup creates a table that is data-bound to the properties of the `detail` observable in the view model.

The "<!-- ko -->" syntax lets you include a Knockout binding outside of a DOM element. In this case, the `if` binding causes this section of markup to be displayed only when `details` is non-null.

```
<!-- ko if:detail() -->
```

Now if you run the app and click one of the "Detail" links, the app will display the book details.

Add a New Item to the Database

2/20/2020 • 2 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

In this section, you will add the ability for users to create a new book. In app.js, add the following code to the view model:

```
self.authors = ko.observableArray();
self.newBook = {
    Author: ko.observable(),
    Genre: ko.observable(),
    Price: ko.observable(),
    Title: ko.observable(),
    Year: ko.observable()
}

var authorsUri = '/api/authors/';

function getAuthors() {
    ajaxHelper(authorsUri, 'GET').done(function (data) {
        self.authors(data);
    });
}

self.addBook = function (formElement) {
    var book = {
        AuthorId: self.newBook.Author().Id,
        Genre: self.newBook.Genre(),
        Price: self.newBook.Price(),
        Title: self.newBook.Title(),
        Year: self.newBook.Year()
    };

    ajaxHelper(booksUri, 'POST', book).done(function (item) {
        self.books.push(item);
    });
}

getAuthors();
```

In Index.cshtml, replace the following markup:

```
<div class="col-md-4">
    <!-- TODO: Add new book -->
</div>
```

With:

```
<div class="col-md-4">
<div class="panel panel-default">
  <div class="panel-heading">
    <h2 class="panel-title">Add Book</h2>
  </div>

  <div class="panel-body">
    <form class="form-horizontal" data-bind="submit: addBook">
      <div class="form-group">
        <label for="inputAuthor" class="col-sm-2 control-label">Author</label>
        <div class="col-sm-10">
          <select data-bind="options:authors, optionsText: 'Name', value: newBook.Author"></select>
        </div>
      </div>

      <div class="form-group" data-bind="with: newBook">
        <label for="inputTitle" class="col-sm-2 control-label">Title</label>
        <div class="col-sm-10">
          <input type="text" class="form-control" id="inputTitle" data-bind="value:Title"/>
        </div>

        <label for="inputYear" class="col-sm-2 control-label">Year</label>
        <div class="col-sm-10">
          <input type="number" class="form-control" id="inputYear" data-bind="value:Year"/>
        </div>

        <label for="inputGenre" class="col-sm-2 control-label">Genre</label>
        <div class="col-sm-10">
          <input type="text" class="form-control" id="inputGenre" data-bind="value:Genre"/>
        </div>

        <label for="inputPrice" class="col-sm-2 control-label">Price</label>
        <div class="col-sm-10">
          <input type="number" step="any" class="form-control" id="inputPrice" data-bind="value:Price"/>
        </div>
      </div>
      <button type="submit" class="btn btn-default">Submit</button>
    </form>
  </div>
</div>
</div>
```

This markup creates a form for submitting a new author. The values for the author drop-down list are data-bound to the `authors` observable in the view model. For the other form inputs, the values are data-bound to the `newBook` property of the view model.

The submit handler on the form is bound to the `addBook` function:

```
<form class="form-horizontal" data-bind="submit: addBook">
```

The `addBook` function reads the current values of the data-bound form inputs to create a JSON object. Then it POSTs the JSON object to `/api/books`.

Publish the App to Azure Azure App Service

2/20/2020 • 2 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

As the last step, you will publish the application to Azure. In Solution Explorer, right-click the project and select **Publish**.

Clicking **Publish** invokes the **Publish Web** dialog. If you checked **Host in Cloud** when you first created the project, then the connection and settings are already configured. In that case, just click the **Settings** tab and check "Execute Code First Migrations". (If you didn't check **Host in Cloud** at the beginning, then follow the steps in the next section.)

To deploy the app, click **Publish**. You can view the publishing progress in the **Web Publish Activity** window. (From the **View** menu, select **Other Windows**, then select **Web Publish Activity**.)

When Visual Studio finishes deploying the app, the default browser automatically opens to the URL of the deployed website, and the application that you created is now running in the cloud. The URL in the browser address bar shows that the site is being loaded from the Internet.

Deploying to a New Website

If you did not check **Host in Cloud** when you first created the project, you can configure a new web app now. In Solution Explorer, right-click the project and select **Publish**. Select the **Profile** tab and click **Microsoft Azure Websites**. If you aren't currently signed in to Azure, you will be prompted to sign in.

In the **Existing Websites** dialog, click **New**.

Enter a site name. Select your Azure subscription and the region. Under **Database server**, select **Create New Server**, or select an existing server. Click **Create**.

Click the **Settings** tab and check "Execute Code First Migrations". Then click **Publish**.

Web API and Mobile Clients

2/20/2020 • 2 minutes to read • Edit Online

Using ASP.NET Web API to reach native mobile clients.

- Calling Web API from a Windows Phone 8 Application (C#)

Calling Web API from a Windows Phone 8 Application (C#)

2/20/2020 • 16 minutes to read • Edit Online

by Robert McMurray

In this tutorial, you will learn how to create a complete end-to-end scenario consisting of an ASP.NET Web API application that provides a catalog of books to a Windows Phone 8 application.

Overview

RESTful services like ASP.NET Web API simplify the creation of HTTP-based applications for developers by abstracting the architecture for server-side and client-side applications. Instead of creating a proprietary socket-based protocol for communication, Web API developers simply need to publish the requisite HTTP methods for their application, (for example: GET, POST, PUT, DELETE), and client application developers only need to consume the HTTP methods that are necessary for their application.

In this end-to-end tutorial, you will learn how to use Web API to create the following projects:

- In the first part of this tutorial, you will create an ASP.NET Web API application that supports all of the Create, Read, Update, and Delete (CRUD) operations to manage a book catalog. This application will use the Sample XML File (books.xml) from MSDN.
- In the second part of this tutorial, you will create an interactive Windows Phone 8 application that retrieves the data from your Web API application.

Prerequisites

- Visual Studio 2013 with the Windows Phone 8 SDK installed
- Windows 8 or later on a 64-bit system with Hyper-V installed
- For a list of additional requirements, see the *System Requirements* section on the Windows Phone SDK 8.0 download page.

> **NOTE**
>
> If you are going to test the connectivity between Web API and Windows Phone 8 projects on your local system, you will need to follow the instructions in the *Connecting the Windows Phone 8 Emulator to Web API Applications on a Local Computer* article to set up your testing environment.

Step 1: Creating the Web API Bookstore Project

The first step of this end-to-end tutorial is to create a Web API project that supports all of the CRUD operations; note that you will add the Windows Phone application project to this solution in Step 2 of this tutorial.

1. Open **Visual Studio 2013**.
2. Click **File**, then **New**, and then **Project**.
3. When the **New Project** dialog box is displayed, expand **Installed**, then **Templates**, then **Visual C#**, and then **Web**.

Click image to expand

4. Highlight **ASP.NET Web Application**, enter **BookStore** for the project name, and then click **OK**.

5. When the **New ASP.NET Project** dialog box is displayed, select the **Web API** template, and then click **OK**.

Click image to expand

6. When the Web API project opens, remove the sample controller from the project:

   a. Expand the **Controllers** folder in the solution explorer.
   b. Right-click the **ValuesController.cs** file, and then click **Delete**.
   c. Click **OK** when prompted to confirm the deletion.

7. Add an XML data file to the Web API project; this file contains the contents of the bookstore catalog:

   a. Right-click the **App_Data** folder in the solution explorer, then click **Add**, and then click **New Item**.

   b. When the **Add New Item** dialog box is displayed, highlight the **XML File** template.

   c. Name the file **Books.xml**, and then click **Add**.

   d. When the **Books.xml** file is opened, replace the code in the file with the XML from the sample **books.xml** file on MSDN:

```
<?xml version="1.0" encoding="utf-8"?>

  </book>
</catalog>
```

e. Save and close the XML file.

8. Add the bookstore model to the Web API project; this model contains the Create, Read, Update, and Delete (CRUD) logic for the bookstore application:

   a. Right-click the **Models** folder in the solution explorer, then click **Add**, and then click **Class**.

   b. When the **Add New Item** dialog box is displayed, name the class file **BookDetails.cs**, and then click **Add**.

   c. When the **BookDetails.cs** file is opened, replace the code in the file with the following:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.Linq;
using System.Xml;
using System.Xml.Linq;
using System.Xml.XPath;
using System.Web;

namespace BookStore.Models
{
    /// <summary>
    /// Define a class that will hold the detailed information for a book.
    /// </summary>
    public class BookDetails
    {
        [Required]
        public String Id { get; set; }
        [Required]
        public String Title { get; set; }
        public String Author { get; set; }
        public String Genre { get; set; }
        public Decimal Price { get; set; }
        public DateTime PublishDate { get; set; }
        public String Description { get; set; }
    }

    /// <summary>
    /// Define an interface which contains the methods for the book repository.
    /// </summary>
    public interface IBookRepository
    {
        BookDetails CreateBook(BookDetails book);
        IEnumerable<BookDetails> ReadAllBooks();
```

```
        BookDetails ReadBook(String id);
        BookDetails UpdateBook(String id, BookDetails book);
        Boolean DeleteBook(String id);
    }

    /// <summary>
    /// Define a class based on the book repository interface which contains the method
implementations.
    /// </summary>
    public class BookRepository : IBookRepository
    {
        private string xmlFilename = null;
        private XDocument xmlDocument = null;

        /// <summary>
        /// Define the class constructor.
        /// </summary>
        public BookRepository()
        {
            try
            {
                // Determine the path to the books.xml file.
                xmlFilename = HttpContext.Current.Server.MapPath("~/app_data/books.xml");
                // Load the contents of the books.xml file into an XDocument object.
                xmlDocument = XDocument.Load(xmlFilename);
            }

        }
    }
}
```

d. Save and close the **BookDetails.cs** file.

9. Add the bookstore controller to the Web API project:

   a. Right-click the **Controllers** folder in the solution explorer, then click **Add**, and then click **Controller**.

   b. When the **Add Scaffold** dialog box is displayed, highlight **Web API 2 Controller - Empty**, and then click **Add**.

   c. When the **Add Controller** dialog box is displayed, name the controller **BooksController**, and then click **Add**.

   d. When the **BooksController.cs** file is opened, replace the code in the file with the following:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Net;
using System.Net.Http;
using System.Web.Http;
using BookStore.Models;

namespace BookStore.Controllers
{
    public class BooksController : ApiController
    {
        private BookRepository repository = null;

        // Define the class constructor.
        public BooksController()
        {
            this.repository = new BookRepository();
        }

        /// <summary>
        /// Method to retrieve all of the books in the catalog.
        /// Example: GET api/books
        /// </summary>
        [HttpGet]
        public HttpResponseMessage Get()
        {
```

```
            IEnumerable<BookDetails> books = this.repository.ReadAllBooks();
            if (books != null)
            {
                return Request.CreateResponse<IEnumerable<BookDetails>>(HttpStatusCode.OK,
books);
            }
            else
            {
                return Request.CreateResponse(HttpStatusCode.NotFound);
            }
        }

        /// <summary>
        /// Method to retrieve a specific book from the catalog.
        /// Example: GET api/books/5
        /// </summary>
        [HttpGet]
        public HttpResponseMessage Get(String id)
        {
            BookDetails book = this.repository.ReadBook(id);
            if (book != null)
            {
                return Request.CreateResponse<BookDetails>(HttpStatusCode.OK, book);
            }
            else
            {
                return Request.CreateResponse(HttpStatusCode.NotFound);
            }
        }

        /// <summary>
        /// Method to add a new book to the catalog.
        /// Example: POST api/books
        /// </summary>
        [HttpPost]
        public HttpResponseMessage Post(BookDetails book)
        {
            if ((this.ModelState.IsValid) && (book != null))
            {
                BookDetails newBook = this.repository.CreateBook(book);
                if (newBook != null)
                {
                    var httpResponse = Request.CreateResponse<BookDetails>

                    string uri = Url.Link("DefaultApi", new { id = newBook.Id });
                    httpResponse.Headers.Location = new Uri(uri);
                    return httpResponse;
                }
            }
            return Request.CreateResponse(HttpStatusCode.BadRequest);
        }

        /// <summary>
        /// Method to update an existing book in the catalog.
        /// Example: PUT api/books/5
        /// </summary>
        [HttpPut]
        public HttpResponseMessage Put(String id, BookDetails book)
        {
            if ((this.ModelState.IsValid) && (book != null) && (book.Id.Equals(id)))
            {
                BookDetails modifiedBook = this.repository.UpdateBook(id, book);
                if (modifiedBook != null)
                {
                    return Request.CreateResponse<BookDetails>(HttpStatusCode.OK, modifiedBook);
                }
                else
                {
                    return Request.CreateResponse(HttpStatusCode.NotFound);
```

```
                }
            }
            return Request.CreateResponse(HttpStatusCode.BadRequest);
        }

        /// <summary>
        /// Method to remove an existing book from the catalog.
        /// Example: DELETE api/books/5
        /// </summary>
        [HttpDelete]
        public HttpResponseMessage Delete(String id)
        {
            BookDetails book = this.repository.ReadBook(id);
            if (book != null)
            {
                if (this.repository.DeleteBook(id))
                {
                    return Request.CreateResponse(HttpStatusCode.OK);
                }
            }
            else
            {
                return Request.CreateResponse(HttpStatusCode.NotFound);
            }
            return Request.CreateResponse(HttpStatusCode.BadRequest);
        }
    }
}
```

e. Save and close the **BooksController.cs** file.

10. Build the Web API application to check for errors.

Step 2: Adding the Windows Phone 8 Bookstore Catalog Project

The next step of this end-to-end scenario is to create the catalog application for Windows Phone 8. This application will use the *Windows Phone Databound App* template for the default user interface, and it will use the Web API application that you created in Step 1 of this tutorial as the data source.

1. Right-click the **BookStore** solution in the in the solution explorer, then click **Add**, and then **New Project**.
2. When the **New Project** dialog box is displayed, expand **Installed**, then **Visual C#**, and then **Windows Phone**.
3. Highlight **Windows Phone Databound App**, enter **BookCatalog** for the name, and then click **OK**.
4. Add the Json.NET NuGet package to the **BookCatalog** project:
   a. Right-click **References** for the **BookCatalog** project in the solution explorer, and then click **Manage NuGet Packages**.
   b. When the **Manage NuGet Packages** dialog box is displayed, expand the **Online** section, and highlight **nuget.org**.
   c. Enter **Json.NET** in the search field and click the search icon.
   d. Highlight **Json.NET** in the search results, and then click **Install**.
   e. When the installation has completed, click **Close**.
5. Add the **BookDetails** model to the **BookCatalog** project; this contains a generic model of the bookstore class:
   a. Right-click the **BookCatalog** project in the solution explorer, then click **Add**, and then click **New Folder**.
   b. Name the new folder **Models**.

c. Right-click the **Models** folder in the solution explorer, then click **Add**, and then click **Class**.

d. When the **Add New Item** dialog box is displayed, name the class file **BookDetails.cs**, and then click **Add**.

e. When the **BookDetails.cs** file is opened, replace the code in the file with the following:

```
using System;
using System.Text;

namespace BookCatalog.Models
{
    /// <summary>
    /// Define a class that will hold the detailed information for a book.
    /// </summary>
    public class BookDetails
    {
        public String Id { get; set; }
        public String Title { get; set; }
        public String Author { get; set; }
        public String Genre { get; set; }
        public Decimal Price { get; set; }
        public DateTime PublishDate { get; set; }
        public String Description { get; set; }
    }
}
```

f. Save and close the **BookDetails.cs** file.

6. Update the **MainViewModel.cs** class to include the functionality to communicate with the BookStore Web API application:

a. Expand the **ViewModels** folder in the solution explorer, and then double-click the **MainViewModel.cs** file.

b. When the **MainViewModel.cs** file is opened, replace the code in the file with the following; note that you will need to update the value of the `apiUrl` constant with the actual URL of your Web API:

```
using System;
using System.Collections.ObjectModel;
using System.ComponentModel;
using System.Net;
using System.Net.NetworkInformation;
using BookCatalog.Resources;
using System.Collections.Generic;
using Newtonsoft.Json;
using BookCatalog.Models;

namespace BookCatalog.ViewModels
{
    public class MainViewModel : INotifyPropertyChanged
    {
        const string apiUrl = @"http://www.contoso.com/api/Books";

        public MainViewModel()
        {
            this.Items = new ObservableCollection<ItemViewModel>();
        }

        /// <summary>
        /// A collection for ItemViewModel objects.
        /// </summary>
        public ObservableCollection<ItemViewModel> Items { get; private set; }
```

```
        public bool IsDataLoaded
        {
            get;
            private set;
        }

        /// <summary>
        /// Creates and adds a few ItemViewModel objects into the Items collection.
        /// </summary>
        public void LoadData()
        {
            if (this.IsDataLoaded == false)
            {
                this.Items.Clear();
                this.Items.Add(new ItemViewModel() { ID = "0", LineOne = "Please Wait...",
LineTwo = "Please wait while the catalog is downloaded from the server.", LineThree = null });
                WebClient webClient = new WebClient();
                webClient.Headers["Accept"] = "application/json";
                webClient.DownloadStringCompleted += new
DownloadStringCompletedEventHandler(webClient_DownloadCatalogCompleted);
                webClient.DownloadStringAsync(new Uri(apiUrl));
            }
        }

        private void webClient_DownloadCatalogCompleted(object sender,
DownloadStringCompletedEventArgs e)
        {
            try
            {
                this.Items.Clear();
                if (e.Result != null)
                {
                    var books = JsonConvert.DeserializeObject<BookDetails[]>(e.Result);
                    int id = 0;
                    foreach (BookDetails book in books)
                    {
                        this.Items.Add(new ItemViewModel()
                        {
                            ID = (id++).ToString(),
                            LineOne = book.Title,
                            LineTwo = book.Author,
                            LineThree = book.Description.Replace("\n", " ")
                        });
                    }
                    this.IsDataLoaded = true;
                }
            }
            catch (Exception ex)
            {
                this.Items.Add(new ItemViewModel()
                {
                    ID = "0",
                    LineOne = "An Error Occurred",
                    LineTwo = String.Format("The following exception occured: {0}", ex.Message),
                    LineThree = String.Format("Additional inner exception information: {0}",
ex.InnerException.Message)
                });
            }
        }

        public event PropertyChangedEventHandler PropertyChanged;
        private void NotifyPropertyChanged(String propertyName)
        {
            PropertyChangedEventHandler handler = PropertyChanged;
            if (null != handler)
            {
                handler(this, new PropertyChangedEventArgs(propertyName));
            }
        }
```

```
    }
}
```

c. Save and close the **MainViewModel.cs** file.

7. Update the **MainPage.xaml** file to customize the application name:

   a. Double-click the **MainPage.xaml** file in the solution explorer.

   b. When the **MainPage.xaml** file is opened, locate the following lines of code:

```
<StackPanel Grid.Row="0" Margin="12,17,0,28">
    <TextBlock Text="MY APPLICATION" Style="{StaticResource PhoneTextNormalStyle}"/>
    <TextBlock Text="page name" Margin="9,-7,0,0" Style="{StaticResource
PhoneTextTitle1Style}"/>
</StackPanel>
```

   c. Replace those lines with the following:

```
<StackPanel Grid.Row="0" Margin="12,17,0,28">
    <TextBlock Text="Book Store" Style="{StaticResource PhoneTextTitle1Style}"/>
    <TextBlock Text="Current Catalog" Margin="9,-7,0,0" Style="{StaticResource
PhoneTextTitle2Style}"/>
</StackPanel>
```

   d. Save and close the **MainPage.xaml** file.

8. Update the **DetailsPage.xaml** file to customize the displayed items:

   a. Double-click the **DetailsPage.xaml** file in the solution explorer.

   b. When the **DetailsPage.xaml** file is opened, locate the following lines of code:

```
<StackPanel x:Name="TitlePanel" Grid.Row="0" Margin="12,17,0,28">
    <TextBlock Text="MY APPLICATION" Style="{StaticResource PhoneTextNormalStyle}"/>
    <TextBlock Text="{Binding LineOne}" Margin="9,-7,0,0" Style="{StaticResource
PhoneTextTitle1Style}"/>
</StackPanel>
```

   c. Replace those lines with the following:

```
<StackPanel x:Name="TitlePanel" Grid.Row="0" Margin="12,17,0,28">
    <TextBlock Text="Book Store" Style="{StaticResource PhoneTextTitle1Style}"/>
    <TextBlock Text="{Binding LineOne}" Margin="9,-7,0,0" Style="{StaticResource
PhoneTextTitle2Style}"/>
</StackPanel>
```

   d. Save and close the **DetailsPage.xaml** file.

9. Build the Windows Phone application to check for errors.

Step 3: Testing the End-to-End Solution

As mentioned in the *Prerequisites* section of this tutorial, when you are testing the connectivity between Web API and Windows Phone 8 projects on your local system, you will need to follow the instructions in the *Connecting the Windows Phone 8 Emulator to Web API Applications on a Local Computer* article to set up your testing environment.

Once you have the testing environment configured, you will need to set the Windows Phone application as the

startup project. To do so, highlight the **BookCatalog** application in the solution explorer, and then click **Set as StartUp Project**:

Click image to expand

When you press F5, Visual Studio will start both the Windows Phone Emulator, which will display a "Please Wait" message while the application data is retrieved from your Web API:

Click image to expand

If everything is successful, you should see the catalog displayed:

Click image to expand

If you tap on any book title, the application will display the book description:

Click image to expand

If the application cannot communicate with your Web API, an error message will be displayed:

Click image to expand

If you tap on the error message, any additional details about the error will be displayed:

Click image to expand

OData in ASP.NET Web API

2/20/2020 • 2 minutes to read • Edit Online

How to create OData endpoints in ASP.NET Web API for ASP.NET 4.x. OData is a data access protocol for the web. It provides a uniform way to query and manipulate data sets. Web API supports both Version 3 and Version 4 of the OData protocol.

- OData v4
  - Create an OData v4 Endpoint
  - Create an OData v4 Client App (C#)
  - Entity Relations in OData v4
  - Actions and Functions in OData v4
  - Containment in OData v4
  - Create a Singleton in OData v4
  - Open Types in OData v4
  - Complex Type Inheritance in OData v4
- OData v3
  - Creating an OData v3 Endpoint
  - Supporting Entity Relations in OData v3
  - OData Actions in Web API 2
  - Calling an OData Service From a .NET Client (C#)
- Supporting OData Query Options in Web API 2
- Using $select, $expand, and $value in Web API 2 OData
- Routing Conventions in Web API 2 OData
- Security Guidance for Web API 2 OData

Supporting OData v4 in ASP.NET Web API

2/20/2020 • 2 minutes to read • Edit Online

Use ASP.NET Web API to create endpoints that support OData Version 4.

- Create an OData v4 Endpoint
- Create an OData v4 Client App (C#)
- Entity Relations in OData v4
- Actions and Functions in OData v4
- Containment in OData v4
- Create a Singleton in OData v4
- Open Types in OData v4
- Complex Type Inheritance in OData v4

Create an OData v4 Endpoint Using ASP.NET Web API

2/20/2020 • 6 minutes to read • Edit Online

The Open Data Protocol (OData) is a data access protocol for the web. OData provides a uniform way to query and manipulate data sets through CRUD operations (create, read, update, and delete).

ASP.NET Web API supports both v3 and v4 of the protocol. You can even have a v4 endpoint that runs side-by-side with a v3 endpoint.

This tutorial shows how to create an OData v4 endpoint that supports CRUD operations.

Software versions used in the tutorial

- Web API 5.2
- OData v4
- Visual Studio 2017 (download Visual Studio 2017 here)
- Entity Framework 6
- .NET 4.7.2

Tutorial versions

For the OData Version 3, see Creating an OData v3 Endpoint.

Create the Visual Studio Project

In Visual Studio, from the **File** menu, select **New** > **Project**.

Expand **Installed** > **Visual C#** > **Web**, and select the **ASP.NET Web Application (.NET Framework)** template. Name the project "ProductService".

Select **OK**.

Select the **Empty** template. Under **Add folders and core references for:**, select **Web API**. Select **OK**.

Install the OData packages

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**. In the Package Manager Console window, type:

```
Install-Package Microsoft.AspNet.Odata
```

This command installs the latest OData NuGet packages.

Add a model class

A *model* is an object that represents a data entity in your application.

In Solution Explorer, right-click the Models folder. From the context menu, select **Add** > **Class**.

> **NOTE**
>
> By convention, model classes are placed in the Models folder, but you don't have to follow this convention in your own projects.

Name the class `Product`. In the Product.cs file, replace the boilerplate code with the following:

```
namespace ProductService.Models
{
    public class Product
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public decimal Price { get; set; }
        public string Category { get; set; }
    }
}
```

The `Id` property is the entity key. Clients can query entities by key. For example, to get the product with ID of 5, the URI is `/Products(5)`. The `Id` property will also be the primary key in the back-end database.

Enable Entity Framework

For this tutorial, we'll use Entity Framework (EF) Code First to create the back-end database.

> **NOTE**
> Web API OData does not require EF. Use any data-access layer that can translate database entities into models.

First, install the NuGet package for EF. From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**. In the Package Manager Console window, type:

```
Install-Package EntityFramework
```

Open the Web.config file, and add the following section inside the **configuration** element, after the **configSections** element.

```
<configuration>
  <configSections>
    <!-- ... -->
  </configSections>

  <!-- Add this: -->
  <connectionStrings>
    <add name="ProductsContext" connectionString="Data Source=(localdb)\mssqllocaldb;
        Initial Catalog=ProductsContext; Integrated Security=True; MultipleActiveResultSets=True;
        AttachDbFilename=|DataDirectory|ProductsContext.mdf"
      providerName="System.Data.SqlClient" />
  </connectionStrings>
```

This setting adds a connection string for a LocalDB database. This database will be used when you run the app locally.

Next, add a class named `ProductsContext` to the Models folder:

```
using System.Data.Entity;
namespace ProductService.Models
{
    public class ProductsContext : DbContext
    {
        public ProductsContext()
                : base("name=ProductsContext")
        {
        }
        public DbSet<Product> Products { get; set; }
    }
}
```

In the constructor, `"name=ProductsContext"` gives the name of the connection string.

Configure the OData endpoint

Open the file App_Start/WebApiConfig.cs. Add the following **using** statements:

```
using ProductService.Models;
using Microsoft.AspNet.OData.Builder;
using Microsoft.AspNet.OData.Extensions;
```

Then add the following code to the **Register** method:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        // New code:
        ODataModelBuilder builder = new ODataConventionModelBuilder();
        builder.EntitySet<Product>("Products");
        config.MapODataServiceRoute(
            routeName: "ODataRoute",
            routePrefix: null,
            model: builder.GetEdmModel());
    }
}
```

This code does two things:

- Creates an Entity Data Model (EDM).
- Adds a route.

An EDM is an abstract model of the data. The EDM is used to create the service metadata document. The **ODataConventionModelBuilder** class creates an EDM by using default naming conventions. This approach requires the least code. If you want more control over the EDM, you can use the **ODataModelBuilder** class to create the EDM by adding properties, keys, and navigation properties explicitly.

A *route* tells Web API how to route HTTP requests to the endpoint. To create an OData v4 route, call the **MapODataServiceRoute** extension method.

If your application has multiple OData endpoints, create a separate route for each. Give each route a unique route name and prefix.

Add the OData controller

A *controller* is a class that handles HTTP requests. You create a separate controller for each entity set in your OData service. In this tutorial, you will create one controller, for the `Product` entity.

In Solution Explorer, right-click the Controllers folder and select **Add** > **Class**. Name the class `ProductsController`.

> **NOTE**
> The version of this tutorial for OData v3 uses the **Add Controller** scaffolding. Currently, there is no scaffolding for OData v4.

Replace the boilerplate code in ProductsController.cs with the following.

```
using ProductService.Models;
using System.Data.Entity;
using System.Data.Entity.Infrastructure;
using System.Linq;
using System.Net;
using System.Threading.Tasks;
using System.Web.Http;
using System.Web.OData;
namespace ProductService.Controllers
{
    public class ProductsController : ODataController
    {
        ProductsContext db = new ProductsContext();
        private bool ProductExists(int key)
        {
            return db.Products.Any(p => p.Id == key);
        }
        protected override void Dispose(bool disposing)
        {
            db.Dispose();
            base.Dispose(disposing);
        }
    }
}
```

The controller uses the `ProductsContext` class to access the database using EF. Notice that the controller overrides the **Dispose** method to dispose of the **ProductsContext**.

This is the starting point for the controller. Next, we'll add methods for all of the CRUD operations.

Query the entity set

Add the following methods to `ProductsController`.

```
[EnableQuery]
public IQueryable<Product> Get()
{
    return db.Products;
}
[EnableQuery]
public SingleResult<Product> Get([FromODataUri] int key)
{
    IQueryable<Product> result = db.Products.Where(p => p.Id == key);
    return SingleResult.Create(result);
}
```

The parameterless version of the `Get` method returns the entire Products collection. The `Get` method with a *key* parameter looks up a product by its key (in this case, the `Id` property).

The **[EnableQuery]** attribute enables clients to modify the query, by using query options such as $filter, $sort, and $page. For more information, see Supporting OData Query Options.

Add an entity to the entity set

To enable clients to add a new product to the database, add the following method to `ProductsController`.

```
public async Task<IHttpActionResult> Post(Product product)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }
    db.Products.Add(product);
    await db.SaveChangesAsync();
    return Created(product);
}
```

Update an entity

OData supports two different semantics for updating an entity, PATCH and PUT.

- PATCH performs a partial update. The client specifies just the properties to update.
- PUT replaces the entire entity.

The disadvantage of PUT is that the client must send values for all of the properties in the entity, including values that are not changing. The OData spec states that PATCH is preferred.

In any case, here is the code for both PATCH and PUT methods:

```
public async Task<IHttpActionResult> Patch([FromODataUri] int key, Delta<Product> product)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }
    var entity = await db.Products.FindAsync(key);
    if (entity == null)
    {
        return NotFound();
    }
    product.Patch(entity);
    try
    {
        await db.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!ProductExists(key))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }
    return Updated(entity);
}
public async Task<IHttpActionResult> Put([FromODataUri] int key, Product update)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }
    if (key != update.Id)
    {
        return BadRequest();
    }
    db.Entry(update).State = EntityState.Modified;
    try
    {
        await db.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!ProductExists(key))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }
    return Updated(update);
}
```

In the case of PATCH, the controller uses the **Delta<T>** type to track the changes.

Delete an entity

To enable clients to delete a product from the database, add the following method to `ProductsController`.

```
public async Task<IHttpActionResult> Delete([FromODataUri] int key)
{
    var product = await db.Products.FindAsync(key);
    if (product == null)
    {
        return NotFound();
    }
    db.Products.Remove(product);
    await db.SaveChangesAsync();
    return StatusCode(HttpStatusCode.NoContent);
}
```

Create an OData v4 Client App (C#)

2/20/2020 • 2 minutes to read • Edit Online

by Mike Wasson

In the previous tutorial, you created a basic OData service that supports CRUD operations. Now let's create a client for the service.

Start a new instance of Visual Studio and create a new console application project. In the **New Project** dialog, select **Installed** > **Templates** > **Visual C#** > **Windows Desktop**, and select the **Console Application** template. Name the project "ProductsApp".

> **NOTE**
>
> You can also add the console app to the same Visual Studio solution that contains the OData service.

Install the OData Client Code Generator

From the **Tools** menu, select **Extensions and Updates**. Select **Online** > **Visual Studio Gallery**. In the search box, search for "OData Client Code Generator". Click **Download** to install the VSIX. You might be prompted to restart Visual Studio.

Run the OData Service Locally

Run the ProductService project from Visual Studio. By default, Visual Studio launches a browser to the application root. Note the URI; you will need this in the next step. Leave the application running.

> **NOTE**
>
> If you put both projects in the same solution, make sure to run the ProductService project without debugging. In the next step, you will need to keep the service running while you modify the console application project.

Generate the Service Proxy

The service proxy is a .NET class that defines methods for accessing the OData service. The proxy translates method calls into HTTP requests. You will create the proxy class by running a T4 template.

Right-click the project. Select **Add** > **New Item**.

In the **Add New Item** dialog, select **Visual C# Items** > **Code** > **OData Client**. Name the template "ProductClient.tt". Click **Add** and click through the security warning.

At this point, you'll get an error, which you can ignore. Visual Studio automatically runs the template, but the template needs some configuration settings first.

Open the file ProductClient.odata.config. In the `Parameter` element, paste in the URI from the ProductService project (previous step). For example:

```
<Parameter Name="MetadataDocumentUri" Value="http://localhost:61635/" />
```

Run the template again. In Solution Explorer, right click the ProductClient.tt file and select **Run Custom Tool**.

The template creates a code file named ProductClient.cs that defines the proxy. As you develop your app, if you change the OData endpoint, run the template again to update the proxy.

Use the Service Proxy to Call the OData Service

Open the file Program.cs and replace the boilerplate code with the following.

```
using System;

namespace ProductsApp
{
    class Program
    {
        // Get an entire entity set.
        static void ListAllProducts(Default.Container container)
        {
            foreach (var p in container.Products)
            {
                Console.WriteLine("{0} {1} {2}", p.Name, p.Price, p.Category);
            }
        }

        static void AddProduct(Default.Container container, ProductService.Models.Product product)
        {
            container.AddToProducts(product);
            var serviceResponse = container.SaveChanges();
            foreach (var operationResponse in serviceResponse)
            {
                Console.WriteLine("Response: {0}", operationResponse.StatusCode);
            }
        }

        static void Main(string[] args)
        {
            // TODO: Replace with your local URI.
            string serviceUri = "http://localhost:port/";
            var container = new Default.Container(new Uri(serviceUri));

            var product = new ProductService.Models.Product()
            {
                Name = "Yo-yo",
                Category = "Toys",
                Price = 4.95M
            };

            AddProduct(container, product);
            ListAllProducts(container);
        }
    }
}
```

Replace the value of *serviceUri* with the service URI from earlier.

```
// TODO: Replace with your local URI.
string serviceUri = "http://localhost:port/";
```

When you run the app, it should output the following:

```
Response: 201
Yo-yo 4.95 Toys
```

Entity Relations in OData v4 Using ASP.NET Web API 2.2

2/20/2020 • 7 minutes to read • Edit Online

by Mike Wasson

Most data sets define relations between entities: Customers have orders; books have authors; products have suppliers. Using OData, clients can navigate over entity relations. Given a product, you can find the supplier. You can also create or remove relationships. For example, you can set the supplier for a product.

This tutorial shows how to support these operations in OData v4 using ASP.NET Web API. The tutorial builds on the tutorial Create an OData v4 Endpoint Using ASP.NET Web API 2.

Software versions used in the tutorial

- Web API 2.1
- OData v4
- Visual Studio 2013 (download Visual Studio 2017 here)
- Entity Framework 6
- .NET 4.5

Tutorial versions

For the OData Version 3, see Supporting Entity Relations in OData v3.

Add a Supplier Entity

> **NOTE**
>
> The tutorial builds on the tutorial Create an OData v4 Endpoint Using ASP.NET Web API 2.

First, we need a related entity. Add a class named `Supplier` in the Models folder.

```
using System.Collections.Generic;

namespace ProductService.Models
{
    public class Supplier
    {
        public int Id { get; set; }
        public string Name { get; set; }

        public ICollection<Product> Products { get; set; }
    }
}
```

Add a navigation property to the `Product` class:

```
using System.ComponentModel.DataAnnotations.Schema;

namespace ProductService.Models
{
    public class Product
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public decimal Price { get; set; }
        public string Category { get; set; }

        // New code:
        [ForeignKey("Supplier")]
        public int? SupplierId { get; set; }
        public virtual Supplier Supplier { get; set; }
    }
}
```

Add a new **DbSet** to the `ProductsContext` class, so that Entity Framework will include the Supplier table in the database.

```
public class ProductsContext : DbContext
{
    static ProductsContext()
    {
        Database.SetInitializer(new ProductInitializer());
    }

    public DbSet<Product> Products { get; set; }
    // New code:
    public DbSet<Supplier> Suppliers { get; set; }
}
```

In WebApiConfig.cs, add a "Suppliers" entity set to the entity data model:

```
public static void Register(HttpConfiguration config)
{
    ODataModelBuilder builder = new ODataConventionModelBuilder();
    builder.EntitySet<Product>("Products");
    // New code:
    builder.EntitySet<Supplier>("Suppliers");
    config.MapODataServiceRoute("ODataRoute", null, builder.GetEdmModel());
}
```

Add a Suppliers Controller

Add a `SuppliersController` class to the Controllers folder.

```
using ProductService.Models;
using System.Linq;
using System.Web.OData;

namespace ProductService.Controllers
{
    public class SuppliersController : ODataController
    {
        ProductsContext db = new ProductsContext();

        protected override void Dispose(bool disposing)
        {
            db.Dispose();
            base.Dispose(disposing);
        }
    }
}
```

I won't show how to add CRUD operations for this controller. The steps are the same as for the Products controller (see Create an OData v4 Endpoint).

Getting Related Entities

To get the supplier for a product, the client sends a GET request:

```
GET /Products(1)/Supplier
```

To support this request, add the following method to the `ProductsController` class:

```
public class ProductsController : ODataController
{
    // GET /Products(1)/Supplier
    [EnableQuery]
    public SingleResult<Supplier> GetSupplier([FromODataUri] int key)
    {
        var result = db.Products.Where(m => m.Id == key).Select(m => m.Supplier);
        return SingleResult.Create(result);
    }

   // Other controller methods not shown.
}
```

This method uses a default naming convention

- Method name: GetX, where X is the navigation property.
- Parameter name: *key*

If you follow this naming convention, Web API automatically maps the HTTP request to the controller method.

Example HTTP request:

```
GET http://myproductservice.example.com/Products(1)/Supplier HTTP/1.1
User-Agent: Fiddler
Host: myproductservice.example.com
```

Example HTTP response:

```
HTTP/1.1 200 OK
Content-Length: 125
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true
Server: Microsoft-IIS/8.0
OData-Version: 4.0
Date: Tue, 08 Jul 2014 00:44:27 GMT

{
  "@odata.context":"http://myproductservice.example.com/$metadata#Suppliers/$entity","Id":2,"Name":"Wingtip
Toys"
}
```

Getting a related collection

In the previous example, a product has one supplier. A navigation property can also return a collection. The following code gets the products for a supplier:

```
public class SuppliersController : ODataController
{
    // GET /Suppliers(1)/Products
    [EnableQuery]
    public IQueryable<Product> GetProducts([FromODataUri] int key)
    {
        return db.Suppliers.Where(m => m.Id.Equals(key)).SelectMany(m => m.Products);
    }

    // Other controller methods not shown.
}
```

In this case, the method returns an **IQueryable** instead of a **SingleResult<T>**

Example HTTP request:

```
GET http://myproductservice.example.com/Suppliers(2)/Products HTTP/1.1
User-Agent: Fiddler
Host: myproductservice.example.com
```

Example HTTP response:

```
HTTP/1.1 200 OK
Content-Length: 372
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true
Server: Microsoft-IIS/8.0
OData-Version: 4.0
Date: Tue, 08 Jul 2014 01:06:54 GMT

{
  "@odata.context":"http://myproductservice.example.com/$metadata#Products","value":[
    {
      "Id":1,"Name":"Hat","Price":14.95,"Category":"Clothing","SupplierId":2
    },{
      "Id":2,"Name":"Socks","Price":6.95,"Category":"Clothing","SupplierId":2
    },{
      "Id":4,"Name":"Pogo Stick","Price":29.99,"Category":"Toys","SupplierId":2
    }
  ]
}
```

Creating a Relationship Between Entities

OData supports creating or removing relationships between two existing entities. In OData v4 terminology, the relationship is a "reference". (In OData v3, the relationship was called a *link*. The protocol differences don't matter for this tutorial.)

A reference has its own URI, with the form `/Entity/NavigationProperty/$ref`. For example, here is the URI to address the reference between a product and its supplier:

```
http:/host/Products(1)/Supplier/$ref
```

To add a relationship, the client sends a POST or PUT request to this address.

- PUT if the navigation property is a single entity, such as `Product.Supplier`.
- POST if the navigation property is a collection, such as `Supplier.Products`.

The body of the request contains the URI of the other entity in the relation. Here is an example request:

```
PUT http://myproductservice.example.com/Products(6)/Supplier/$ref HTTP/1.1
OData-Version: 4.0;NetFx
OData-MaxVersion: 4.0;NetFx
Accept: application/json;odata.metadata=minimal
Accept-Charset: UTF-8
Content-Type: application/json;odata.metadata=minimal
User-Agent: Microsoft ADO.NET Data Services
Host: myproductservice.example.com
Content-Length: 70
Expect: 100-continue

{"@odata.id":"http://myproductservice.example.com/Suppliers(4)"}
```

In this example, the client sends a PUT request to `/Products(6)/Supplier/$ref`, which is the $ref URI for the `Supplier` of the product with ID = 6. If the request succeeds, the server sends a 204 (No Content) response:

```
HTTP/1.1 204 No Content
Server: Microsoft-IIS/8.0
Date: Tue, 08 Jul 2014 06:35:59 GMT
```

Here is the controller method to add a relationship to a `Product`:

```
public class ProductsController : ODataController
{
    [AcceptVerbs("POST", "PUT")]
    public async Task<IHttpActionResult> CreateRef([FromODataUri] int key,
        string navigationProperty, [FromBody] Uri link)
    {
        var product = await db.Products.SingleOrDefaultAsync(p => p.Id == key);
        if (product == null)
        {
            return NotFound();
        }
        switch (navigationProperty)
        {
            case "Supplier":
                // Note: The code for GetKeyFromUri is shown later in this topic.
                var relatedKey = Helpers.GetKeyFromUri<int>(Request, link);
                var supplier = await db.Suppliers.SingleOrDefaultAsync(f => f.Id == relatedKey);
                if (supplier == null)
                {
                    return NotFound();
                }

                product.Supplier = supplier;
                break;

            default:
                return StatusCode(HttpStatusCode.NotImplemented);
        }
        await db.SaveChangesAsync();
        return StatusCode(HttpStatusCode.NoContent);
    }

    // Other controller methods not shown.
}
```

The *navigationProperty* parameter specifies which relationship to set. (If there is more than one navigation property on the entity, you can add more `case` statements.)

The *link* parameter contains the URI of the supplier. Web API automatically parses the request body to get the value for this parameter.

To look up the supplier, we need the ID (or key), which is part of the *link* parameter. To do this, use the following helper method:

```
using Microsoft.OData.Core;
using Microsoft.OData.Core.UriParser;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Net.Http;
using System.Web.Http.Routing;
using System.Web.OData.Extensions;
using System.Web.OData.Routing;

namespace ProductService
{
    public static class Helpers
    {
        public static TKey GetKeyFromUri<TKey>(HttpRequestMessage request, Uri uri)
        {
            if (uri == null)
            {
                throw new ArgumentNullException("uri");
            }

            var urlHelper = request.GetUrlHelper() ?? new UrlHelper(request);

            string serviceRoot = urlHelper.CreateODataLink(
                request.ODataProperties().RouteName,
                request.ODataProperties().PathHandler, new List<ODataPathSegment>());
            var odataPath = request.ODataProperties().PathHandler.Parse(
                request.ODataProperties().Model,
                serviceRoot, uri.LocalPath);

            var keySegment = odataPath.Segments.OfType<KeyValuePathSegment>().FirstOrDefault();
            if (keySegment == null)
            {
                throw new InvalidOperationException("The link does not contain a key.");
            }

            var value = ODataUriUtils.ConvertFromUriLiteral(keySegment.Value, ODataVersion.V4);
            return (TKey)value;
        }

    }
}
```

Basically, this method uses the OData library to split the URI path into segments, find the segment that contains the key, and convert the key into the correct type.

Deleting a Relationship Between Entities

To delete a relationship, the client sends an HTTP DELETE request to the $ref URI:

```
DELETE http://host/Products(1)/Supplier/$ref
```

Here is the controller method to delete the relationship between a Product and a Supplier:

```
public class ProductsController : ODataController
{
    public async Task<IHttpActionResult> DeleteRef([FromODataUri] int key,
        string navigationProperty, [FromBody] Uri link)
    {
        var product = db.Products.SingleOrDefault(p => p.Id == key);
        if (product == null)
        {
            return NotFound();
        }

        switch (navigationProperty)
        {
            case "Supplier":
                product.Supplier = null;
                break;

            default:
                return StatusCode(HttpStatusCode.NotImplemented);
        }
        await db.SaveChangesAsync();

        return StatusCode(HttpStatusCode.NoContent);
    }

    // Other controller methods not shown.
}
```

In this case, `Product.Supplier` is the "1" end of a 1-to-many relation, so you can remove the relationship just by setting `Product.Supplier` to `null`.

In the "many" end of a relationship, the client must specify which related entity to remove. To do so, the client sends the URI of the related entity in the query string of the request. For example, to remove "Product 1" from "Supplier 1":

```
DELETE http://host/Suppliers(1)/Products/$ref?$id=http://host/Products(1)
```

To support this in Web API, we need to include an extra parameter in the `DeleteRef` method. Here is the controller method to remove a product from the `Supplier.Products` relation.

```
public class SuppliersController : ODataController
{
    public async Task<IHttpActionResult> DeleteRef([FromODataUri] int key,
        [FromODataUri] string relatedKey, string navigationProperty)
    {
        var supplier = await db.Suppliers.SingleOrDefaultAsync(p => p.Id == key);
        if (supplier == null)
        {
            return StatusCode(HttpStatusCode.NotFound);
        }

        switch (navigationProperty)
        {
            case "Products":
                var productId = Convert.ToInt32(relatedKey);
                var product = await db.Products.SingleOrDefaultAsync(p => p.Id == productId);

                if (product == null)
                {
                    return NotFound();
                }
                product.Supplier = null;
                break;
            default:
                return StatusCode(HttpStatusCode.NotImplemented);

        }
        await db.SaveChangesAsync();

        return StatusCode(HttpStatusCode.NoContent);
    }

    // Other controller methods not shown.
}
```

The *key* parameter is the key for the supplier, and the *relatedKey* parameter is the key for the product to remove from the `Products` relationship. Note that Web API automatically gets the key from the query string.

Actions and Functions in OData v4 Using ASP.NET Web API 2.2

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

In OData, actions and functions are a way to add server-side behaviors that are not easily defined as CRUD operations on entities. This tutorial shows how to add actions and functions to an OData v4 endpoint, using Web API 2.2. The tutorial builds on the tutorial Create an OData v4 Endpoint Using ASP.NET Web API 2

Software versions used in the tutorial

- Web API 2.2
- OData v4
- Visual Studio 2013 (download Visual Studio 2017 here)
- .NET 4.5

Tutorial versions

For OData Version 3, see OData Actions in ASP.NET Web API 2.

The difference between *actions* and *functions* is that actions can have side effects, and functions do not. Both actions and functions can return data. Some uses for actions include:

- Complex transactions.
- Manipulating several entities at once.
- Allowing updates only to certain properties of an entity.
- Sending data that is not an entity.

Functions are useful for returning information that does not correspond directly to an entity or collection.

An action (or function) can target a single entity or a collection. In OData terminology, this is the *binding*. You can also have "unbound" actions/functions, which are called as static operations on the service.

Example: Adding an Action

Let's define an action to rate a product.

> **NOTE**
>
> This tutorial builds on the tutorial Create an OData v4 Endpoint Using ASP.NET Web API 2

First, add a `ProductRating` model to represent the ratings.

```
namespace ProductService.Models
{
    public class ProductRating
    {
        public int ID { get; set; }
        public int Rating { get; set; }
        public int ProductID { get; set; }
        public virtual Product Product { get; set; }
    }
}
```

Also add a **DbSet** to the `ProductsContext` class, so that EF will create a Ratings table in the database.

```
public class ProductsContext : DbContext
{
    public ProductsContext()
            : base("name=ProductsContext")
    {
    }

    public DbSet<Product> Products { get; set; }
    public DbSet<Supplier> Suppliers { get; set; }
    // New code:
    public DbSet<ProductRating> Ratings { get; set; }
}
```

Add the Action to the EDM

In WebApiConfig.cs, add the following code:

```
ODataModelBuilder builder = new ODataConventionModelBuilder();
builder.EntitySet<Product>("Products");

// New code:
builder.Namespace = "ProductService";
builder.EntityType<Product>()
    .Action("Rate")
    .Parameter<int>("Rating");
```

The **EntityTypeConfiguration.Action** method adds an action to the entity data model (EDM). The **Parameter** method specifies a typed parameter for the action.

This code also sets the namespace for the EDM. The namespace matters because the URI for the action includes the fully-qualified action name:

```
http://localhost/Products(1)/ProductService.Rate
```

> **NOTE**
>
> In a typical IIS configuration, the dot in this URL will cause IIS to return error 404. You can resolve this by adding the following section to your Web.Config file:

```
<system.webServer>
    <handlers>
      <clear/>
      <add name="ExtensionlessUrlHandler-Integrated-4.0" path="/*"
          verb="*" type="System.Web.Handlers.TransferRequestHandler"
          preCondition="integratedMode,runtimeVersionv4.0" />
    </handlers>
</system.webServer>
```

Add a Controller Method for the Action

To enable the "Rate" action, add the following method to `ProductsController`:

```
[HttpPost]
public async Task<IHttpActionResult> Rate([FromODataUri] int key, ODataActionParameters parameters)
{
    if (!ModelState.IsValid)
    {
        return BadRequest();
    }

    int rating = (int)parameters["Rating"];
    db.Ratings.Add(new ProductRating
    {
        ProductID = key,
        Rating = rating
    });

    try
    {
        await db.SaveChangesAsync();
    }
    catch (DbUpdateException e)
    {
        if (!ProductExists(key))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return StatusCode(HttpStatusCode.NoContent);
}
```

Notice that the method name matches the action name. The **[HttpPost]** attribute specifies the method is an HTTP POST method.

To invoke the action, the client sends an HTTP POST request like the following:

```
POST http://localhost/Products(1)/ProductService.Rate HTTP/1.1
Content-Type: application/json
Content-Length: 12

{"Rating":5}
```

The "Rate" action is bound to Product instances, so the URI for the action is the fully-qualified action name appended to the entity URI. (Recall that we set the EDM namespace to "ProductService", so the fully-qualified action name is "ProductService.Rate".)

The body of the request contains the action parameters as a JSON payload. Web API automatically converts the JSON payload to an **ODataActionParameters** object, which is just a dictionary of parameter values. Use this dictionary to access the parameters in your controller method.

If the client sends the action parameters in the wrong format, the value of **ModelState.IsValid** is false. Check this flag in your controller method and return an error if **IsValid** is false.

```
if (!ModelState.IsValid)
{
    return BadRequest();
}
```

Example: Adding a Function

Now let's add an OData function that returns the most expensive product. As before, the first step is adding the function to the EDM. In WebApiConfig.cs, add the following code.

```
ODataModelBuilder builder = new ODataConventionModelBuilder();
builder.EntitySet<Product>("Products");
builder.EntitySet<Supplier>("Suppliers");

// New code:
builder.Namespace = "ProductService";
builder.EntityType<Product>().Collection
    .Function("MostExpensive")
    .Returns<double>();
```

In this case, the function is bound to the Products collection, rather than individual Product instances. Clients invoke the function by sending a GET request:

```
GET http://localhost:38479/Products/ProductService.MostExpensive
```

Here is the controller method for this function:

```
public class ProductsController : ODataController
{
    [HttpGet]
    public IHttpActionResult MostExpensive()
    {
        var product = db.Products.Max(x => x.Price);
        return Ok(product);
    }

    // Other controller methods not shown.
}
```

Notice that the method name matches the function name. The **[HttpGet]** attribute specifies the method is an HTTP GET method.

Here is the HTTP response:

```
HTTP/1.1 200 OK
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true
OData-Version: 4.0
Date: Sat, 28 Jun 2014 00:44:07 GMT
Content-Length: 85

{
  "@odata.context":"http://localhost:38479/$metadata#Edm.Decimal","value":50.00
}
```

Example: Adding an Unbound Function

The previous example was a function bound to a collection. In this next example, we'll create an *unbound* function. Unbound functions are called as static operations on the service. The function in this example will return the sales tax for a given postal code.

In the WebApiConfig file, add the function to the EDM:

```
ODataModelBuilder builder = new ODataConventionModelBuilder();
builder.EntitySet<Product>("Products");

// New code:
builder.Function("GetSalesTaxRate")
    .Returns<double>()
    .Parameter<int>("PostalCode");
```

Notice that we are calling **Function** directly on the **ODataModelBuilder**, instead of the entity type or collection. This tells the model builder that the function is unbound.

Here is the controller method that implements the function:

```
[HttpGet]
[ODataRoute("GetSalesTaxRate(PostalCode={postalCode})")]
public IHttpActionResult GetSalesTaxRate([FromODataUri] int postalCode)
{
    double rate = 5.6;  // Use a fake number for the sample.
    return Ok(rate);
}
```

It does not matter which Web API controller you place this method in. You could put it in `ProductsController`, or define a separate controller. The **[ODataRoute]** attribute defines the URI template for the function.

Here is an example client request:

```
GET http://localhost:38479/GetSalesTaxRate(PostalCode=10) HTTP/1.1
```

The HTTP response:

```
HTTP/1.1 200 OK
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true
OData-Version: 4.0
Date: Sat, 28 Jun 2014 01:05:32 GMT
Content-Length: 82

{
  "@odata.context":"http://localhost:38479/$metadata#Edm.Double","value":5.6
}
```

Containment in OData v4 Using Web API 2.2

9/16/2020 • 3 minutes to read • Edit Online

by Jinfu Tan

> Traditionally, an entity could only be accessed if it were encapsulated inside an entity set. But OData v4 provides two additional options, Singleton and Containment, both of which WebAPI 2.2 supports.

This topic shows how to define a containment in an OData endpoint in WebApi 2.2. For more information about containment, see Containment is coming with OData v4. To create an OData V4 endpoint in Web API, see Create an OData v4 Endpoint Using ASP.NET Web API 2.2.

First, we'll create a containment domain model in the OData service, using this data model:

An account contains many PaymentInstruments (PI), but we don't define an entity set for a PI. Instead, the PIs can only be accessed through an Account.

You can download the solution used in this topic from CodePlex.

Defining the data model

1. Define the CLR types.

```
public class Account
{
    public int AccountID { get; set; }
    public string Name { get; set; }
    [Contained]
    public IList<PaymentInstrument> PayinPIs { get; set; }
}

public class PaymentInstrument
{
    public int PaymentInstrumentID { get; set; }
    public string FriendlyName { get; set; }
}
```

   The `Contained` attribute is used for containment navigation properties.

2. Generate the EDM model based on the CLR types.

```
public static IEdmModel GetModel()
{
    ODataConventionModelBuilder builder = new ODataConventionModelBuilder();
    builder.EntitySet<Account>("Accounts");
    var paymentInstrumentType = builder.EntityType<PaymentInstrument>();
    var functionConfiguration =
        paymentInstrumentType.Collection.Function("GetCount");
    functionConfiguration.Parameter<string>("NameContains");
    functionConfiguration.Returns<int>();
    builder.Namespace = typeof(Account).Namespace;
    return builder.GetEdmModel();
}
```

The `ODataConventionModelBuilder` will handle building the EDM model if the `Contained` attribute is added to the corresponding navigation property. If the property is a collection type, a `GetCount(string NameContains)` function will also be created.

The generated metadata will look like the following:

```
<EntityType Name="Account">
  <Key>
    <PropertyRef Name="AccountID" />
  </Key>
  <Property Name="AccountID" Type="Edm.Int32" Nullable="false" />
  <Property Name="Name" Type="Edm.String" />
  <NavigationProperty
    Name="PayinPIs"
    Type="Collection(ODataContrainmentSample.PaymentInstrument)"
    ContainsTarget="true" />
</EntityType>
```

The `ContainsTarget` attribute indicates that the navigation property is a containment.

Define the containing entity set controller

Contained entities don't have their own controller; the action is defined in the containing entity set controller. In this sample, there is an AccountsController, but no PaymentInstrumentsController.

```
public class AccountsController : ODataController
{
    private static IList<Account> _accounts = null;
    public AccountsController()
    {
        if (_accounts == null)
        {
            _accounts = InitAccounts();
        }
    }
    // PUT ~/Accounts(100)/PayinPIs
    [EnableQuery]
    public IHttpActionResult GetPayinPIs(int key)
    {
        var payinPIs = _accounts.Single(a => a.AccountID == key).PayinPIs;
        return Ok(payinPIs);
    }
    [EnableQuery]
    [ODataRoute("Accounts({accountId})/PayinPIs({paymentInstrumentId})")]
    public IHttpActionResult GetSinglePayinPI(int accountId, int paymentInstrumentId)
    {
        var payinPIs = _accounts.Single(a => a.AccountID == accountId).PayinPIs;
        var payinPI = payinPIs.Single(pi => pi.PaymentInstrumentID == paymentInstrumentId);
        return Ok(payinPI);
```

```
    }
    // PUT ~/Accounts(100)/PayinPIs(101)
    [ODataRoute("Accounts({accountId})/PayinPIs({paymentInstrumentId})")]
    public IHttpActionResult PutToPayinPI(int accountId, int paymentInstrumentId, [FromBody]PaymentInstrument
paymentInstrument)
    {
        var account = _accounts.Single(a => a.AccountID == accountId);
        var originalPi = account.PayinPIs.Single(p => p.PaymentInstrumentID == paymentInstrumentId);
        originalPi.FriendlyName = paymentInstrument.FriendlyName;
        return Ok(paymentInstrument);
    }
    // DELETE ~/Accounts(100)/PayinPIs(101)
    [ODataRoute("Accounts({accountId})/PayinPIs({paymentInstrumentId})")]
    public IHttpActionResult DeletePayinPIFromAccount(int accountId, int paymentInstrumentId)
    {
        var account = _accounts.Single(a => a.AccountID == accountId);
        var originalPi = account.PayinPIs.Single(p => p.PaymentInstrumentID == paymentInstrumentId);
        if (account.PayinPIs.Remove(originalPi))
        {
            return StatusCode(HttpStatusCode.NoContent);
        }
        else
        {
            return StatusCode(HttpStatusCode.InternalServerError);
        }
    }
    // GET ~/Accounts(100)/PayinPIs/Namespace.GetCount()
    [ODataRoute("Accounts({accountId})/PayinPIs/ODataContrainmentSample.GetCount(NameContains={name})")]
    public IHttpActionResult GetPayinPIsCountWhoseNameContainsGivenValue(int accountId, [FromODataUri]string
name)
    {
        var account = _accounts.Single(a => a.AccountID == accountId);
        var count = account.PayinPIs.Where(pi => pi.FriendlyName.Contains(name)).Count();
        return Ok(count);
    }
    private static IList<Account> InitAccounts()
    {
        var accounts = new List<Account>()
        {
            new Account()
            {
                AccountID = 100,
                Name="Name100",
                PayinPIs = new List<PaymentInstrument>()
                {
                    new PaymentInstrument()
                    {
                        PaymentInstrumentID = 101,
                        FriendlyName = "101 first PI",
                    },
                    new PaymentInstrument()
                    {
                        PaymentInstrumentID = 102,
                        FriendlyName = "102 second PI",
                    },
                },
            },
        };
        return accounts;
    }
}
```

If the OData path is 4 or more segments, only attribute routing works, such as `[ODataRoute("Accounts({accountId})/PayinPIs({paymentInstrumentId})")]` in the above controller. Otherwise, both attribute and conventional routing works: for instance, `GetPayInPIs(int key)` matches `GET ~/Accounts(1)/PayinPIs`.

Create a Singleton in OData v4 Using Web API 2.2

2/20/2020 • 3 minutes to read • Edit Online

by Zoe Luo

> Traditionally, an entity could only be accessed if it were encapsulated inside an entity set. But OData v4 provides two additional options, Singleton and Containment, both of which WebAPI 2.2 supports.

This article shows how to define a singleton in an OData endpoint in Web API 2.2. For information on what a singleton is and how you can benefit from using it, see Using a singleton to define your special entity. To create an OData V4 endpoint in Web API, see Create an OData v4 Endpoint Using ASP.NET Web API 2.2.

We'll create a singleton in your Web API project using the following data model:

A singleton named `Umbrella` will be defined based on type `Company`, and an entity set named `Employees` will be defined based on type `Employee`.

The solution used in this tutorial can be downloaded from CodePlex.

Define the data model

1. Define the CLR types.

```
/// <summary>
/// Present the EntityType "Employee"
/// </summary>
public class Employee
{
    public int ID { get; set; }
    public string Name { get; set; }

    [Singleton]
    public Company Company { get; set; }
}
/// <summary>
/// Present company category, which is an enum type
/// </summary>
public enum CompanyCategory
{
    IT = 0,
    Communication = 1,
    Electronics = 2,
    Others = 3
}
/// <summary>
/// Present the EntityType "Company"
/// </summary>
public class Company
{
     public int ID { get; set; }
     public string Name { get; set; }
     public Int64 Revenue { get; set; }
     public CompanyCategory Category { get; set; }
     public List<Employee> Employees { get; set; }
}
```

2. Generate the EDM model based on the CLR types.

```
public static IEdmModel GetEdmModel()
{
    ODataConventionModelBuilder builder = new ODataConventionModelBuilder();
    builder.EntitySet<Employee>("Employees"); builder.Singleton<Company>("Umbrella");
    builder.Namespace = typeof(Company).Namespace;
    return builder.GetEdmModel();
}
```

Here, `builder.Singleton<Company>("Umbrella")` tells the model builder to create a singleton named `Umbrella` in the EDM model.

The generated metadata will look like the following:

```
<EntityContainer Name="Container">
  <EntitySet Name="Employees" EntityType="ODataSingletonSample.Employee">
    <NavigationPropertyBinding Path="Company" Target="Umbrella"/>
  </EntitySet>
  <Singleton Name="Umbrella" Type="ODataSingletonSample.Company">
    <NavigationPropertyBinding Path="Employees" Target="Employees"/>
  </Singleton>
</EntityContainer>
```

From the metadata we can see that the navigation property `Company` in the `Employees` entity set is bound to the singleton `Umbrella`. The binding is done automatically by `ODataConventionModelBuilder`, since only `Umbrella` has the `Company` type. If there is any ambiguity in the model, you can use `HasSingletonBinding` to explicitly bind a navigation property to a singleton; `HasSingletonBinding` has the same effect as using the

`Singleton` attribute in the CLR type definition:

```
EntitySetConfiguration<Employee> employeesConfiguration =
    builder.EntitySet<Employee>("Employees");
employeesConfiguration.HasSingletonBinding(c => c.Company, "Umbrella");
```

Define the singleton controller

Like the EntitySet controller, the singleton controller inherits from `ODataController`, and the singleton controller name should be `[singletonName]Controller`.

```
public class UmbrellaController : ODataController
{
    public static Company Umbrella;
    static UmbrellaController()
    {
        InitData();
    }
    private static void InitData()
    {
        Umbrella = new Company()
        {
            ID = 1,
            Name = "Umbrella",
            Revenue = 1000,
            Category = CompanyCategory.Communication,
            Employees = new List<Employee>()
        };
    }
}
```

In order to handle different kinds of requests, actions are required to be pre-defined in the controller. **Attribute routing** is enabled by default in WebApi 2.2. For example, to define an action to handle querying `Revenue` from `Company` using attribute routing, use the following:

```
[ODataRoute("Umbrella/Revenue")]
public IHttpActionResult GetCompanyRevenue()
{
     return Ok(Umbrella.Revenue);
}
```

If you are not willing to define attributes for each action, just define your actions following OData Routing Conventions. Since a key is not required for querying a singleton, the actions defined in the singleton controller are slightly different from actions defined in the entityset controller.

For reference, method signatures for every action definition in the singleton controller are listed below.

```
// Get Singleton
// ~/singleton
public IHttpActionResult Get()
public IHttpActionResult GetUmbrella()

// Get Singleton
// ~/singleton/cast
public IHttpActionResult GetFromSubCompany()
public IHttpActionResult GetUmbrellaFromSubCompany()

// Get Singleton Property
// ~/singleton/property
public IHttpActionResult GetName()
public IHttpActionResult GetNameFromCompany()

// Get Singleton Navigation Property
// ~/singleton/navigation
public IHttpActionResult GetEmployees()
public IHttpActionResult GetEmployeesFromCompany()

// Update singleton by PUT
// PUT ~/singleton
public IHttpActionResult Put(Company newCompany)
public IHttpActionResult PutUmbrella(Company newCompany)

// Update singleton by Patch
// PATCH ~/singleton
public IHttpActionResult Patch(Delta<Company> item)
public IHttpActionResult PatchUmbrella(Delta<Company> item)

// Add navigation link to singleton
// POST ~/singleton/navigation/$ref
public IHttpActionResult CreateRef(string navigationProperty, [FromBody] Uri link)

// Delete navigation link from singleton
// DELETE ~/singleton/navigation/$ref?$id=~/relatedKey
public IHttpActionResult DeleteRef(string relatedKey, string navigationProperty)

// Add a new entity to singleton navigation property
// POST ~/singleton/navigation
public IHttpActionResult PostToEmployees([FromBody] Employee employee)

// Call function bounded to singleton
// GET ~/singleton/function()
public IHttpActionResult GetEmployeesCount()
```

Basically, this is all you need to do on the service side. The sample project contains all of the code for the solution and the OData client that shows how to use the singleton. The client is built by following the steps in Create an OData v4 Client App.

.

Open Types in OData v4 with ASP.NET Web API

4/10/2020 • 5 minutes to read • Edit Online

by Microsoft

In OData v4, an *open type* is a structured type that contains dynamic properties, in addition to any properties that are declared in the type definition. Open types let you add flexibility to your data models. This tutorial shows how to use open types in ASP.NET Web API OData.

This tutorial assumes that you already know how to create an OData endpoint in ASP.NET Web API. If not, start by reading Create an OData v4 Endpoint first.

Software versions used in the tutorial

- Web API OData 5.3
- OData v4

First, some OData terminology:

- Entity type: A structured type with a key.
- Complex type: A structured type without a key.
- Open type: A type with dynamic properties. Both entity types and complex types can be open.

The value of a dynamic property can be a primitive type, complex type, or enumeration type; or a collection of any of those types. For more information about open types, see the OData v4 specification.

Install the Web OData Libraries

Use NuGet Package Manager to install the latest Web API OData libraries. From the Package Manager Console window:

```
Install-Package Microsoft.AspNet.OData
Install-Package Microsoft.AspNet.WebApi.OData
```

Define the CLR Types

Start by defining the EDM models as CLR types.

```
public enum Category
{
    Book,
    Magazine,
    EBook
}

public class Address
{
    public string City { get; set; }
    public string Street { get; set; }
}

public class Customer
{
    public int Id { get; set; }
    public string Name { get; set; }
    public Address Address { get; set; }
}

public class Press
{
    public string Name { get; set; }
    public string Email { get; set; }
    public Category Category { get; set; }
    public IDictionary<string, object> DynamicProperties { get; set; }
}

public class Book
{
    [Key]
    public string ISBN { get; set; }
    public string Title { get; set; }
    public Press Press { get; set; }
    public IDictionary<string, object> Properties { get; set; }
}
```

When the Entity Data Model (EDM) is created,

- `Category` is an enumeration type.
- `Address` is a complex type. (It does not have a key, so it is not an entity type.)
- `Customer` is an entity type. (It has a key.)
- `Press` is an open complex type.
- `Book` is an open entity type.

To create an open type, the CLR type must have a property of type `IDictionary<string, object>`, which holds the dynamic properties.

Build the EDM Model

If you use **ODataConventionModelBuilder** to create the EDM, `Press` and `Book` are automatically added as open types, based on the presence of a `IDictionary<string, object>` property.

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        ODataConventionModelBuilder builder = new ODataConventionModelBuilder();
        builder.EntitySet<Book>("Books");
        builder.EntitySet<Customer>("Customers");
        var model = builder.GetEdmModel();

        config.MapODataServiceRoute(
            routeName: "ODataRoute",
            routePrefix: null,
            model: model);

    }
}
```

You can also build the EDM explicitly, using **ODataModelBuilder**.

```
ODataModelBuilder builder = new ODataModelBuilder();

ComplexTypeConfiguration<Press> pressType = builder.ComplexType<Press>();
pressType.Property(c => c.Name);
// ...
pressType.HasDynamicProperties(c => c.DynamicProperties);

EntityTypeConfiguration<Book> bookType = builder.EntityType<Book>();
bookType.HasKey(c => c.ISBN);
bookType.Property(c => c.Title);
// ...
bookType.ComplexProperty(c => c.Press);
bookType.HasDynamicProperties(c => c.Properties);

// ...
builder.EntitySet<Book>("Books");
IEdmModel model = builder.GetEdmModel();
```

Add an OData Controller

Next, add an OData controller. For this tutorial, we'll use a simplified controller that just supports GET and POST requests, and uses an in-memory list to store entities.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web.Http;
using System.Web.OData;

namespace MyApp.Controllers
{
    public class BooksController : ODataController
    {
        private IList<Book> _books = new List<Book>
        {
            new Book
            {
                ISBN = "978-0-7356-8383-9",
                Title = "SignalR Programming in Microsoft ASP.NET",
                Press = new Press
                {
                    Name = "Microsoft Press",
                    Category = Category.Book
                }
```

```
            },

            new Book
            {
                ISBN = "978-0-7356-7942-9",
                Title = "Microsoft Azure SQL Database Step by Step",
                Press = new Press
                {
                    Name = "Microsoft Press",
                    Category = Category.EBook,
                    DynamicProperties = new Dictionary<string, object>
                    {
                        { "Blog", "https://blogs.msdn.com/b/microsoft_press/" },
                        { "Address", new Address {
                              City = "Redmond", Street = "One Microsoft Way" }
                        }
                    }
                },
                Properties = new Dictionary<string, object>
                {
                    { "Published", new DateTimeOffset(2014, 7, 3, 0, 0, 0, 0, new TimeSpan(0))},
                    { "Authors", new [] { "Leonard G. Lobel", "Eric D. Boyd" }},
                    { "OtherCategories", new [] {Category.Book, Category.Magazine}}
                }
            }
        };

        [EnableQuery]
        public IQueryable<Book> Get()
        {
            return _books.AsQueryable();
        }

        public IHttpActionResult Get([FromODataUri]string key)
        {
            Book book = _books.FirstOrDefault(e => e.ISBN == key);
            if (book == null)
            {
                return NotFound();
            }

            return Ok(book);
        }

        public IHttpActionResult Post(Book book)
        {
            if (!ModelState.IsValid)
            {
                return BadRequest(ModelState);
            }
            // For this sample, we aren't enforcing unique keys.
            _books.Add(book);
            return Created(book);
        }
    }
}
```

Notice that the first `Book` instance has no dynamic properties. The second `Book` instance has the following dynamic properties:

- "Published": Primitive type
- "Authors": Collection of primitive types
- "OtherCategories": Collection of enumeration types.

Also, the `Press` property of that `Book` instance has the following dynamic properties:

- "Blog": Primitive type
- "Address": Complex type

Query the Metadata

To get the OData metadata document, send a GET request to `~/$metadata`. The response body should look similar to this:

```
<?xml version="1.0" encoding="utf-8"?>
<edmx:Edmx Version="4.0" xmlns:edmx="http://docs.oasis-open.org/odata/ns/edmx">
  <edmx:DataServices>
    <Schema Namespace="MyApp.Models" xmlns="http://docs.oasis-open.org/odata/ns/edm">
      <EntityType Name="Book" OpenType="true">
        <Key>
          <PropertyRef Name="ISBN" />
        </Key>
        <Property Name="ISBN" Type="Edm.String" Nullable="false" />
        <Property Name="Title" Type="Edm.String" />
        <Property Name="Press" Type="MyApp.Models.Press" />
      </EntityType>
      <EntityType Name="Customer">
        <Key>
          <PropertyRef Name="Id" />
        </Key>
        <Property Name="Id" Type="Edm.Int32" Nullable="false" />
        <Property Name="Name" Type="Edm.String" />
        <Property Name="Address" Type="MyApp.Models.Address" />
      </EntityType>
      <ComplexType Name="Press" OpenType="true">
        <Property Name="Name" Type="Edm.String" />
        <Property Name="Category" Type="MyApp.Models.Category" Nullable="false" />
      </ComplexType>
      <ComplexType Name="Address">
        <Property Name="City" Type="Edm.String" />
        <Property Name="Street" Type="Edm.String" />
      </ComplexType>
      <EnumType Name="Category">
        <Member Name="Book" Value="0" />
        <Member Name="Magazine" Value="1" />
        <Member Name="EBook" Value="2" />
      </EnumType>
    </Schema>
    <Schema Namespace="Default" xmlns="http://docs.oasis-open.org/odata/ns/edm">
      <EntityContainer Name="Container">
        <EntitySet Name="Books" EntityType="MyApp.Models.Book" />
        <EntitySet Name="Customers" EntityType="MyApp.Models.Customer" />
      </EntityContainer>
    </Schema>
  </edmx:DataServices>
</edmx:Edmx>
```

From the metadata document, you can see that:

- For the `Book` and `Press` types, the value of the `OpenType` attribute is true. The `Customer` and `Address` types don't have this attribute.
- The `Book` entity type has three declared properties: ISBN, Title, and Press. The OData metadata does not include the `Book.Properties` property from the CLR class.
- Similarly, the `Press` complex type has only two declared properties: Name and Category. The metadata does not include the `Press.DynamicProperties` property from the CLR class.

Query an Entity

To get the book with ISBN equal to "978-0-7356-7942-9", send a GET request to `~/Books('978-0-7356-7942-9')`. The response body should look similar to the following. (Indented to make it more readable.)

```
{
  "@odata.context":"http://localhost:37141/$metadata#Books/$entity",
    "ISBN":"978-0-7356-7942-9",
    "Title":"Microsoft Azure SQL Database Step by Step",
    "Press":{
      "Name":"Microsoft Press",
      "Category":"EBook",
      "Blog":"https://blogs.msdn.com/b/microsoft_press/",
      "Address":{
        "@odata.type":"#MyApp.Models.Address",
        "City":"Redmond",
        "Street":"One Microsoft Way"
      }
  },
  "Published":"2014-07-03T00:00:00Z",
  "Authors@odata.type":"#Collection(String)",
  "Authors":[
    "Leonard G. Lobel","Eric D. Boyd"
  ],
  "OtherCategories@odata.type":"#Collection(MyApp.Models.Category)",
  "OtherCategories":[
    "Book","Magazine"
  ]
}
```

Notice that the dynamic properties are included inline with the declared properties.

POST an Entity

To add a Book entity, send a POST request to `~/Books`. The client can set dynamic properties in the request payload.

Here is an example request. Note the "Price" and "Published" properties.

```
POST http://localhost:37141/Books HTTP/1.1
User-Agent: Fiddler
Host: localhost:37141
Content-Type: application/json
Content-Length: 191

{
  "ISBN":"978-0-7356-8383-9","Title":"Programming Microsoft ASP.NET MVC","Press":{
  "Name":"Microsoft Press","Category":"Book"
   }, "Price": 49.99, "Published":"2014-02-15T00:00:00Z"
}
```

If you set a breakpoint in the controller method, you can see that Web API added these properties to the `Properties` dictionary.

```
public IHttpActionResult Post(Book book)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }
    _books.Add(book);
    return Create
}

}
}
```

book {WebApplication1.Models.Book}
ISBN "978-0-7356-8383-9"
Press {WebApplication1.Models.Press}
Properties Count = 2
[0] {[Price, 49.99]}
[1] {[Published, 2014-02-15T00:00:00Z]}
Raw View

OData Open Type Sample

Complex Type Inheritance in OData v4 with ASP.NET Web API

4/10/2020 • 3 minutes to read • Edit Online

by Microsoft

According to the OData v4 specification, a complex type can inherit from another complex type. (A *complex* type is a structured type without a key.) Web API OData 5.3 supports complex type inheritance.

This topic shows how to build an entity data model (EDM) with complex inheritance types. For the complete source code, see OData Complex Type Inheritance Sample.

Software versions used in the tutorial

- Web API OData 5.3
- OData v4

Model Hierarchy

To illustrate complex type inheritance, we'll use the following class hierarchy.

`Shape` is an abstract complex type. `Rectangle`, `Triangle`, and `Circle` are complex types derived from `Shape`, and `RoundRectangle` derives from `Rectangle`. `Window` is an entity type and contains a `Shape` instance.

Here are the CLR classes that define these types.

```
public class Window
{
    public int Id { get; set; }
    public string Title { get; set; }
    public Shape Shape { get; set; }
}

public abstract class Shape
{
    public bool HasBorder { get; set; }
    public Color Color { get; set; }
}

public class Rectangle : Shape
{
    public Point LeftTop { get; set; }
    public int Height { get; set; }
    public int Weight { get; set; }
}

public class RoundRectangle : Rectangle
{
    public double Round { get; set; }
}

public class Triangle : Shape
{
    public Point P1 { get; set; }
    public Point P2 { get; set; }
    public Point P3 { get; set; }
}

public class Circle : Shape
{
    public Point Center { get; set; }
    public int Radius { get; set; }
}

public class Point
{
    public int X { get; set; }
    public int Y { get; set; }
}

public enum Color
{
    Red,
    Blue,
    Green,
    Yellow
}
```

Build the EDM Model

To create the EDM, you can use **ODataConventionModelBuilder**, which infers the inheritance relationships from the CLR types.

```
private IEdmModel GetEdmModel()
{
    ODataConventionModelBuilder builder = new ODataConventionModelBuilder();
    builder.EntitySet<Window>("Windows");
    return builder.GetEdmModel();
}
```

You can also build the EDM explicitly, using **ODataModelBuilder**. This takes more code, but gives you more control over the EDM.

```
private IEdmModel GetExplicitEdmModel()
{
  ODataModelBuilder builder = new ODataModelBuilder();

  EnumTypeConfiguration<Color> color = builder.EnumType<Color>();
  color.Member(Color.Red);
  color.Member(Color.Blue);
  color.Member(Color.Green);
  color.Member(Color.Yellow);

  ComplexTypeConfiguration<Point> point = builder.ComplexType<Point>();
  point.Property(c => c.X);
  point.Property(c => c.Y);

  ComplexTypeConfiguration<Shape> shape = builder.ComplexType<Shape>();
  shape.EnumProperty(c => c.Color);
  shape.Property(c => c.HasBorder);
  shape.Abstract();

  ComplexTypeConfiguration<Triangle> triangle = builder.ComplexType<Triangle>();
    triangle.ComplexProperty(c => c.P1);
    triangle.ComplexProperty(c => c.P2);
    triangle.ComplexProperty(c => c.P2);
    triangle.DerivesFrom<Shape>();

    ComplexTypeConfiguration<Rectangle> rectangle = builder.ComplexType<Rectangle>();
    rectangle.ComplexProperty(c => c.LeftTop);
    rectangle.Property(c => c.Height);
    rectangle.Property(c => c.Weight);
    rectangle.DerivesFrom<Shape>();

  ComplexTypeConfiguration<RoundRectangle> roundRectangle = builder.ComplexType<RoundRectangle>();
    roundRectangle.Property(c => c.Round);
    roundRectangle.DerivesFrom<Rectangle>();

    ComplexTypeConfiguration<Circle> circle = builder.ComplexType<Circle>();
    circle.ComplexProperty(c => c.Center);
    circle.Property(c => c.Radius);
    circle.DerivesFrom<Shape>();

    EntityTypeConfiguration<Window> window = builder.EntityType<Window>();
    window.HasKey(c => c.Id);
    window.Property(c => c.Title);
    window.ComplexProperty(c => c.Shape);

    builder.EntitySet<Window>("Windows");
    return builder.GetEdmModel();
}
```

These two examples create the same EDM schema.

Metadata Document

Here is the OData metadata document, showing complex type inheritance.

```
<?xml version="1.0" encoding="utf-8"?>
<edmx:Edmx Version="4.0" xmlns:edmx="http://docs.oasis-open.org/odata/ns/edmx">
  <edmx:DataServices>
    <Schema Namespace="NS" xmlns="http://docs.oasis-open.org/odata/ns/edm">
      <EntityType Name="Window">
        <Key>
          <PropertyRef Name="Id" />
        </Key>
        <Property Name="Id" Type="Edm.Int32" Nullable="false" />
        <Property Name="Title" Type="Edm.String" />
        <Property Name="Shape" Type="BookStore.Shape" />
      </EntityType>
      <ComplexType Name="Shape" Abstract="true">
        <Property Name="HasBorder" Type="Edm.Boolean" Nullable="false" />
        <Property Name="Color" Type="BookStore.Color" Nullable="false" />
      </ComplexType>
      <ComplexType Name="Circle" BaseType="BookStore.Shape">
        <Property Name="Center" Type="BookStore.Point" />
        <Property Name="Radius" Type="Edm.Int32" Nullable="false" />
      </ComplexType>
      <ComplexType Name="Point">
        <Property Name="X" Type="Edm.Int32" Nullable="false" />
        <Property Name="Y" Type="Edm.Int32" Nullable="false" />
      </ComplexType>
      <ComplexType Name="Rectangle" BaseType="BookStore.Shape">
        <Property Name="LeftTop" Type="BookStore.Point" />
        <Property Name="Height" Type="Edm.Int32" Nullable="false" />
        <Property Name="Weight" Type="Edm.Int32" Nullable="false" />
      </ComplexType>
      <ComplexType Name="RoundRectangle" BaseType="BookStore.Rectangle">
        <Property Name="Round" Type="Edm.Double" Nullable="false" />
      </ComplexType>
      <ComplexType Name="Triangle" BaseType="BookStore.Shape">
        <Property Name="P1" Type="BookStore.Point" />
        <Property Name="P2" Type="BookStore.Point" />
        <Property Name="P3" Type="BookStore.Point" />
      </ComplexType>
      <EnumType Name="Color">
        <Member Name="Red" Value="0" />
        <Member Name="Blue" Value="1" />
        <Member Name="Green" Value="2" />
        <Member Name="Yellow" Value="3" />
      </EnumType>
    </Schema>
    <Schema Namespace="Default" xmlns="http://docs.oasis-open.org/odata/ns/edm">
      <EntityContainer Name="Container">
        <EntitySet Name="Windows" EntityType="BookStore.Window" />
      </EntityContainer>
    </Schema>
  </edmx:DataServices>
</edmx:Edmx>
```

From the metadata document, you can see that:

- The `Shape` complex type is abstract.
- The `Rectangle`, `Triangle`, and `Circle` complex type have the base type `Shape`.
- The `RoundRectangle` type has the base type `Rectangle`.

Casting Complex Types

Casting on complex types is now supported. For example, the following query casts a `Shape` to a `Rectangle`.

```
GET ~/odata/Windows(1)/Shape/NS.Rectangle/LeftTop
```

Here's the response payload:

```
{
   "@odata.context":"http://localhost/odata/$metadata#Windows(1)/Shape/NS.Rectangle/LeftTop",
    "X":100,"Y":100
}
```

Supporting OData v3 in ASP.NET Web API

2/20/2020 • 2 minutes to read • Edit Online

Use ASP.NET Web API to create endpoints that support OData Version 3.

- Creating an OData v3 Endpoint
- Supporting Entity Relations in OData v3
- OData Actions in Web API 2
- Calling an OData Service From a .NET Client (C#)

Creating an OData v3 Endpoint with Web API 2

2/20/2020 • 10 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

The Open Data Protocol (OData) is a data access protocol for the web. OData provides a uniform way to structure data, query the data, and manipulate the data set through CRUD operations (create, read, update, and delete). OData supports both AtomPub (XML) and JSON formats. OData also defines a way to expose metadata about the data. Clients can use the metadata to discover the type information and relationships for the data set.

ASP.NET Web API makes it easy to create an OData endpoint for a data set. You can control exactly which OData operations the endpoint supports. You can host multiple OData endpoints, alongside non-OData endpoints. You have full control over your data model, back-end business logic, and data layer.

Software versions used in the tutorial

- Visual Studio 2013
- Web API 2
- OData Version 3
- Entity Framework 6
- Fiddler Web Debugging Proxy (Optional)

Web API OData support was added in ASP.NET and Web Tools 2012.2 Update. However, this tutorial uses scaffolding that was added in Visual Studio 2013.

In this tutorial, you will create a simple OData endpoint that clients can query. You will also create a C# client for the endpoint. After you complete this tutorial, the next set of tutorials show how to add more functionality, including entity relations, actions, and $expand/$select.

- Create the Visual Studio Project
- Add an Entity Model
- Add an OData Controller
- Add the EDM and Route
- Seed the Database (Optional)
- Exploring the OData Endpoint
- OData Serialization Formats

Create the Visual Studio Project

In this tutorial, you will create an OData endpoint that supports basic CRUD operations. The endpoint will expose a single resource, a list of products. Later tutorials will add more features.

Start Visual Studio and select **New Project** from the Start page. Or, from the **File** menu, select **New** and then **Project**.

In the **Templates** pane, select **Installed Templates** and expand the Visual C# node. Under **Visual C#**, select **Web**. Select **the ASP.NET Web Application** template.

In the **New ASP.NET Project** dialog, select the **Empty** template. Under "Add folders and core references for...", check **Web API**. Click **OK**.

Add an Entity Model

A *model* is an object that represents the data in your application. For this tutorial, we need a model that represents a product. The model corresponds to our OData entity type.

In Solution Explorer, right-click the Models folder. From the context menu, select **Add** then select **Class**.

In the **Add New** Item dialog, name the class "Product".

> **NOTE**
>
> By convention, model classes are placed in the Models folder. You don't have to follow this convention in your own projects, but we'll use it for this tutorial.

In the Product.cs file, add the following class definition:

```
public class Product
{
    public int ID { get; set; }
    public string Name { get; set; }
    public decimal Price { get; set; }
    public string Category { get; set; }
}
```

The ID property will be the entity key. Clients can query products by ID. This field would also be the primary key in the back-end database.

Build the project now. In the next step, we'll use some Visual Studio scaffolding that uses reflection to find the Product type.

Add an OData Controller

A *controller* is a class that handles HTTP requests. You define a separate controller for each entity set in you OData service. In this tutorial, we'll create a single controller.

In Solution Explorer, right-click the Controllers folder. Select **Add** and then select **Controller**.

In the **Add Scaffold** dialog, select "Web API 2 OData Controller with actions, using Entity Framework".

In the **Add Controller** dialog, name the controller "ProductsController". Select the "Use async controller actions" checkbox. In the **Model** drop-down list, select the Product class.

Click the **New data context...** button. Leave the default name for the data context type, and click **Add**.

Click Add in the Add Controller dialog to add the controller.

Note: If you get an error message that says "There was an error getting the type...", make sure that you built the Visual Studio project after you added the Product class. The scaffolding uses reflection to find the class.

The scaffolding adds two code files to the project:

- Products.cs defines the Web API controller that implements the OData endpoint.
- ProductServiceContext.cs provides methods to query the underlying database, using Entity Framework.

Add the EDM and Route

In Solution Explorer, expand the App_Start folder and open the file named WebApiConfig.cs. This class holds configuration code for Web API. Replace this code with the following:

```
using ProductService.Models;
using System.Web.Http;
using System.Web.Http.OData.Builder;

namespace ProductService
{
    public static class WebApiConfig
    {
        public static void Register(HttpConfiguration config)
        {
            ODataConventionModelBuilder builder = new ODataConventionModelBuilder();
            builder.EntitySet<Product>("Products");
            config.Routes.MapODataRoute("odata", "odata", builder.GetEdmModel());
        }
    }
}
```

This code does two things:

- Creates an Entity Data Model (EDM) for the OData endpoint.
- Adds a route for the endpoint.

An EDM is an abstract model of the data. The EDM is used to create the metadata document and define the URIs for the service. The **ODataConventionModelBuilder** creates an EDM by using a set of default naming conventions EDM. This approach requires the least code. If you want more control over the EDM, you can use the **ODataModelBuilder** class to create the EDM by adding properties, keys, and navigation properties explicitly.

The **EntitySet** method adds an entity set to the EDM:

```
modelBuilder.EntitySet<Product>("Products");
```

The string "Products" defines the name of the entity set. The name of the controller must match the name of the entity set. In this tutorial, the entity set is named "Products" and the controller is named `ProductsController`. If you named the entity set "ProductSet", you would name the controller `ProductSetController`. Note that an endpoint can have multiple entity sets. Call **EntitySet<T>** for each entity set, and then define a corresponding controller.

The **MapODataRoute** method adds a route for the OData endpoint.

```
config.Routes.MapODataRoute("ODataRoute", "odata", model);
```

The first parameter is a friendly name for the route. Clients of your service do not see this name. The second parameter is the URI prefix for the endpoint. Given this code, the URI for the Products entity set is http://*hostname*/odata/Products. Your application can have more than one OData endpoint. For each endpoint, call **MapODataRoute** and provide a unique route name and a unique URI prefix.

Seed the Database (Optional)

In this step, you will use Entity Framework to seed the database with some test data. This step is optional, but it lets you test out your OData endpoint right away.

From the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the

Package Manager Console window, enter the following command:

```
Enable-Migrations
```

This adds a folder named Migrations and a code file named Configuration.cs.

Open this file and add the following code to the `Configuration.Seed` method.

```
protected override void Seed(ProductService.Models.ProductServiceContext context)
{
    // New code
    context.Products.AddOrUpdate(new Product[] {
        new Product() { ID = 1, Name = "Hat", Price = 15, Category = "Apparel" },
        new Product() { ID = 2, Name = "Socks", Price = 5, Category = "Apparel" },
        new Product() { ID = 3, Name = "Scarf", Price = 12, Category = "Apparel" },
        new Product() { ID = 4, Name = "Yo-yo", Price = 4.95M, Category = "Toys" },
        new Product() { ID = 5, Name = "Puzzle", Price = 8, Category = "Toys" },
    });
}
```

In the Package Manager Console Window, enter the following commands:

```
Add-Migration Initial
Update-Database
```

These commands generate code that creates the database, and then executes that code.

Exploring the OData Endpoint

In this section, we'll use the Fiddler Web Debugging Proxy to send requests to the endpoint and examine the response messages. This will help you to understand the capabilities of an OData endpoint.

In Visual Studio, press F5 to start debugging. By default, Visual Studio opens your browser to `http://localhost:*port*`, where *port* is the port number configured in the project settings.

You can change the port number in the project settings. In Solution Explorer, right-click the project and select **Properties**. In the properties window, select **Web**. Enter the port number under **Project Url**.

Service Document

The *service document* contains a list of the entity sets for the OData endpoint. To get the service document, send a GET request to the root URI of the service.

Using Fiddler, enter the following URI in the **Composer** tab: `http://localhost:port/odata/`, where *port* is the port number.

Click the **Execute** button. Fiddler sends an HTTP GET request to your application. You should see the response in the Web Sessions list. If everything is working, the status code will be 200.

Double-click the response in the Web Sessions list to see the details of the response message in the Inspectors tab.

The raw HTTP response message should look similar to the following:

```
HTTP/1.1 200 OK
Cache-Control: no-cache
Pragma: no-cache
Content-Type: application/atomsvc+xml; charset=utf-8
Expires: -1
Server: Microsoft-IIS/8.0
DataServiceVersion: 3.0
Date: Mon, 23 Sep 2013 17:51:01 GMT
Content-Length: 364

<?xml version="1.0" encoding="utf-8"?>
<service xml:base="http://localhost:60868/odata"
    xmlns="http://www.w3.org/2007/app" xmlns:atom="http://www.w3.org/2005/Atom">
  <workspace>
    <atom:title type="text">Default</atom:title>
    <collection href="Products">
        <atom:title type="text">Products</atom:title>
    </collection>
    </workspace>
</service></pre>
```

By default, Web API returns the service document in AtomPub format. To request JSON, add the following header to the HTTP request:

```
Accept: application/json
```

Now the HTTP response contains a JSON payload:

```
HTTP/1.1 200 OK
Cache-Control: no-cache
Pragma: no-cache
Content-Type: application/json; charset=utf-8
Expires: -1
Server: Microsoft-IIS/8.0
DataServiceVersion: 3.0
Date: Mon, 23 Sep 2013 22:59:28 GMT
Content-Length: 136

{
  "odata.metadata":"http://localhost:60868/odata/$metadata","value":[
    {
      "name":"Products","url":"Products"
    }
  ]
}
```

Service Metadata Document

The *service metadata document* describes the data model of the service, using an XML language called the Conceptual Schema Definition Language (CSDL). The metadata document shows the structure of the data in the service, and can be used to generate client code.

To get the metadata document, send a GET request to `http://localhost:port/odata/$metadata`. Here is the metadata for the endpoint shown in this tutorial.

```
HTTP/1.1 200 OK
Cache-Control: no-cache
Pragma: no-cache
Content-Type: application/xml; charset=utf-8
Expires: -1
Server: Microsoft-IIS/8.0
DataServiceVersion: 3.0
Date: Mon, 23 Sep 2013 23:05:52 GMT
Content-Length: 1086

<?xml version="1.0" encoding="utf-8"?>
<edmx:Edmx Version="1.0" xmlns:edmx="http://schemas.microsoft.com/ado/2007/06/edmx">
  <edmx:DataServices m:DataServiceVersion="3.0" m:MaxDataServiceVersion="3.0"
    xmlns:m="http://schemas.microsoft.com/ado/2007/08/dataservices/metadata">
    <Schema Namespace="ProductService.Models" xmlns="http://schemas.microsoft.com/ado/2009/11/edm">
      <EntityType Name="Product">
        <Key>
          <PropertyRef Name="ID" />
        </Key>
        <Property Name="ID" Type="Edm.Int32" Nullable="false" />
        <Property Name="Name" Type="Edm.String" />
        <Property Name="Price" Type="Edm.Decimal" Nullable="false" />
        <Property Name="Category" Type="Edm.String" />
      </EntityType>
    </Schema>
    <Schema Namespace="Default" xmlns="http://schemas.microsoft.com/ado/2009/11/edm">
      <EntityContainer Name="Container" m:IsDefaultEntityContainer="true">
        <EntitySet Name="Products" EntityType="ProductService.Models.Product" />
      </EntityContainer>
    </Schema>
  </edmx:DataServices>
</edmx:Edmx>
```

Entity Set

To get the Products entity set, send a GET request to `http://localhost:port/odata/Products`.

```
HTTP/1.1 200 OK
Cache-Control: no-cache
Pragma: no-cache
Content-Type: application/json; charset=utf-8
Expires: -1
Server: Microsoft-IIS/8.0
DataServiceVersion: 3.0
Date: Mon, 23 Sep 2013 23:01:31 GMT
Content-Length: 459

{
  "odata.metadata":"http://localhost:60868/odata/$metadata#Products","value":[
    {
      "ID":1,"Name":"Hat","Price":"15.00","Category":"Apparel"
    },{
      "ID":2,"Name":"Socks","Price":"5.00","Category":"Apparel"
    },{
      "ID":3,"Name":"Scarf","Price":"12.00","Category":"Apparel"
    },{
      "ID":4,"Name":"Yo-yo","Price":"4.95","Category":"Toys"
    },{
      "ID":5,"Name":"Puzzle","Price":"8.00","Category":"Toys"
    }
  ]
}
```

Entity

To get an individual product, send a GET request to `http://localhost:port/odata/Products(1)`, where "1" is the product ID.

```
HTTP/1.1 200 OK
Cache-Control: no-cache
Pragma: no-cache
Content-Type: application/json; charset=utf-8
Expires: -1
Server: Microsoft-IIS/8.0
DataServiceVersion: 3.0
Date: Mon, 23 Sep 2013 23:04:29 GMT
Content-Length: 140

{
  "odata.metadata":"http://localhost:60868/odata/$metadata#Products/@Element","ID":1,
      "Name":"Hat","Price":"15.00","Category":"Apparel"
}
```

OData Serialization Formats

OData supports several serialization formats:

- Atom Pub (XML)
- JSON "light" (introduced in OData v3)
- JSON "verbose" (OData v2)

By default, Web API uses AtomPubJSON "light" format.

To get AtomPub format, set the Accept header to "application/atom+xml". Here is an example response body:

```
<?xml version="1.0" encoding="utf-8"?>
<entry xml:base="http://localhost:60868/odata" xmlns="http://www.w3.org/2005/Atom"
xmlns:d="http://schemas.microsoft.com/ado/2007/08/dataservices"
xmlns:m="http://schemas.microsoft.com/ado/2007/08/dataservices/metadata"
xmlns:georss="http://www.georss.org/georss" xmlns:gml="http://www.opengis.net/gml">
  <id>http://localhost:60868/odata/Products(1)</id>
  <category term="ProductService.Models.Product"
scheme="http://schemas.microsoft.com/ado/2007/08/dataservices/scheme" />
  <link rel="edit" href="http://localhost:60868/odata/Products(1)" />
  <link rel="self" href="http://localhost:60868/odata/Products(1)" />
  <title />
  <updated>2013-09-23T23:42:11Z</updated>
  <author>
    <name />
  </author>
  <content type="application/xml">
    <m:properties>
      <d:ID m:type="Edm.Int32">1</d:ID>
      <d:Name>Hat</d:Name>
      <d:Price m:type="Edm.Decimal">15.00</d:Price>
      <d:Category>Apparel</d:Category>
    </m:properties>
  </content>
</entry>
```

You can see one obvious disadvantage of the Atom format: It's a lot more verbose than the JSON light. However, if you have a client that understands AtomPub, the client might prefer that format over JSON.

Here is the JSON light version of the same entity:

```
{
  "odata.metadata":"http://localhost:60868/odata/$metadata#Products/@Element",
  "ID":1,
  "Name":"Hat",
  "Price":"15.00",
  "Category":"Apparel"
}
```

The JSON light format was introduced in version 3 of the OData protocol. For backward compatibility, a client can request the older "verbose" JSON format. To request verbose JSON, set the Accept header to `application/json;odata=verbose`. Here is the verbose version:

```
{
  "d":{
    "__metadata":{
      "id":"http://localhost:18285/odata/Products(1)",
      "uri":"http://localhost:18285/odata/Products(1)",
      "type":"ProductService.Models.Product"
    },"ID":1,"Name":"Hat","Price":"15.00","Category":"Apparel"
  }
}
```

This format conveys more metadata in the response body, which can add considerable overhead over an entire session. Also, it adds a level of indirection by wrapping the object in a property named "d".

Next Steps

- Add Entity Relations
- Add OData Actions
- Call the OData Service From a .NET Client

Supporting Entity Relations in OData v3 with Web API 2

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

Most data sets define relations between entities: Customers have orders; books have authors; products have suppliers. Using OData, clients can navigate over entity relations. Given a product, you can find the supplier. You can also create or remove relationships. For example, you can set the supplier for a product.

This tutorial shows how to support these operations in ASP.NET Web API. The tutorial builds on the tutorial Creating an OData v3 Endpoint with Web API 2.

Software versions used in the tutorial

- Web API 2
- OData Version 3
- Entity Framework 6

Add a Supplier Entity

First we need to add a new entity type to our OData feed. We'll add a `Supplier` class.

```
using System.ComponentModel.DataAnnotations;

namespace ProductService.Models
{
    public class Supplier
    {
        [Key]
        public string Key { get; set; }
        public string Name { get; set; }
    }
}
```

This class uses a string for the entity key. In practice, that might be less common than using an integer key. But it's worth seeing how OData handles other key types besides integers.

Next, we'll create a relation by adding a `Supplier` property to the `Product` class:

```
public class Product
{
    public int ID { get; set; }
    public string Name { get; set; }
    public decimal Price { get; set; }
    public string Category { get; set; }

    // New code
    [ForeignKey("Supplier")]
    public string SupplierId { get; set; }
    public virtual Supplier Supplier { get; set; }
}
```

Add a new **DbSet** to the `ProductServiceContext` class, so that Entity Framework will include the `Supplier` table in the database.

```
public class ProductServiceContext : DbContext
{
    public ProductServiceContext() : base("name=ProductServiceContext")
    {
    }

    public System.Data.Entity.DbSet<ProductService.Models.Product> Products { get; set; }
    // New code:
    public System.Data.Entity.DbSet<ProductService.Models.Supplier> Suppliers { get; set; }
}
```

In WebApiConfig.cs, add a "Suppliers" entity to the EDM model:

```
ODataConventionModelBuilder builder = new ODataConventionModelBuilder();
builder.EntitySet<Product>("Products");
// New code:
builder.EntitySet<Supplier>("Suppliers");
```

Navigation Properties

To get the supplier for a product, the client sends a GET request:

```
GET /Products(1)/Supplier
```

Here "Supplier" is a navigation property on the `Product` type. In this case, `Supplier` refers to a single item, but a navigation property can also return a collection (one-to-many or many-to-many relation).

To support this request, add the following method to the `ProductsController` class:

```
// GET /Products(1)/Supplier
public Supplier GetSupplier([FromODataUri] int key)
{
    Product product = _context.Products.FirstOrDefault(p => p.ID == key);
    if (product == null)
    {
        throw new HttpResponseException(HttpStatusCode.NotFound);
    }
    return product.Supplier;
}
```

The *key* parameter is the key of the product. The method returns the related entity—in this case, a `Supplier`

instance. The method name and parameter name are both important. In general, if the navigation property is named "X", you need to add a method named "GetX". The method must take a parameter named "*key*" that matches the data type of the parent's key.

It is also important to include the **[FromODataUri]** attribute in the *key* parameter. This attribute tells Web API to use OData syntax rules when it parses the key from the request URI.

Creating and Deleting Links

OData supports creating or removing relationships between two entities. In OData terminology, the relationship is a "link." Each link has a URI with the form *entity*/$links/*entity*. For example, the link from product to supplier looks like this:

```
/Products(1)/$links/Supplier
```

To create a new link, the client sends a POST request to the link URI. The body of the request is the URI of the target entity. For example, suppose there is a supplier with the key "CTSO". To create a link from "Product(1)" to "Supplier('CTSO')", the client sends a request like the following:

```
POST http://localhost/odata/Products(1)/$links/Supplier
Content-Type: application/json
Content-Length: 50

{"url":"http://localhost/odata/Suppliers('CTSO')"}
```

To delete a link, the client sends a DELETE request to the link URI.

Creating Links

To enable a client to create product-supplier links, add the following code to the `ProductsController` class:

```
[AcceptVerbs("POST", "PUT")]
public async Task<IHttpActionResult> CreateLink([FromODataUri] int key, string navigationProperty, [FromBody]
Uri link)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    Product product = await db.Products.FindAsync(key);
    if (product == null)
    {
        return NotFound();
    }

    switch (navigationProperty)
    {
        case "Supplier":
            string supplierKey = GetKeyFromLinkUri<string>(link);
            Supplier supplier = await db.Suppliers.FindAsync(supplierKey);
            if (supplier == null)
            {
                return NotFound();
            }
            product.Supplier = supplier;
            await db.SaveChangesAsync();
            return StatusCode(HttpStatusCode.NoContent);

        default:
            return NotFound();
    }
}
```

This method takes three parameters:

- *key*: The key to the parent entity (the product)
- *navigationProperty*: The name of the navigation property. In this example, the only valid navigation property is "Supplier".
- *link*: The OData URI of the related entity. This value is taken from the request body. For example, the link URI might be "`http://localhost/odata/Suppliers('CTSO')`, meaning the supplier with ID = 'CTSO'.

The method uses the link to look up the supplier. If the matching supplier is found, the method sets the `Product.Supplier` property and saves the result to the database.

The hardest part is parsing the link URI. Basically, you need to simulate the result of sending a GET request to that URI. The following helper method shows how to do this. The method invokes the Web API routing process and gets back an **ODataPath** instance that represents the parsed OData path. For a link URI, one of the segments should be the entity key. (If not, the client sent a bad URI.)

```
// Helper method to extract the key from an OData link URI.
private TKey GetKeyFromLinkUri<TKey>(Uri link)
{
    TKey key = default(TKey);

    // Get the route that was used for this request.
    IHttpRoute route = Request.GetRouteData().Route;

    // Create an equivalent self-hosted route.
    IHttpRoute newRoute = new HttpRoute(route.RouteTemplate,
        new HttpRouteValueDictionary(route.Defaults),
        new HttpRouteValueDictionary(route.Constraints),
        new HttpRouteValueDictionary(route.DataTokens), route.Handler);

    // Create a fake GET request for the link URI.
    var tmpRequest = new HttpRequestMessage(HttpMethod.Get, link);

    // Send this request through the routing process.
    var routeData = newRoute.GetRouteData(
        Request.GetConfiguration().VirtualPathRoot, tmpRequest);

    // If the GET request matches the route, use the path segments to find the key.
    if (routeData != null)
    {
        ODataPath path = tmpRequest.GetODataPath();
        var segment = path.Segments.OfType<KeyValuePathSegment>().FirstOrDefault();
        if (segment != null)
        {
            // Convert the segment into the key type.
            key = (TKey)ODataUriUtils.ConvertFromUriLiteral(
                segment.Value, ODataVersion.V3);
        }
    }
    return key;
}
```

Deleting Links

To delete a link, add the following code to the `ProductsController` class:

```
public async Task<IHttpActionResult> DeleteLink([FromODataUri] int key, string navigationProperty)
{
    Product product = await db.Products.FindAsync(key);
    if (product == null)
    {
        return NotFound();
    }

    switch (navigationProperty)
    {
        case "Supplier":
            product.Supplier = null;
            await db.SaveChangesAsync();
            return StatusCode(HttpStatusCode.NoContent);

        default:
            return NotFound();

    }
}
```

In this example, the navigation property is a single `Supplier` entity. If the navigation property is a collection, the URI to delete a link must include a key for the related entity. For example:

```
DELETE /odata/Customers(1)/$links/Orders(1)
```

This request removes order 1 from customer 1. In this case, the DeleteLink method will have the following signature:

```
void DeleteLink([FromODataUri] int key, string relatedKey, string navigationProperty);
```

The *relatedKey* parameter gives the key for the related entity. So in your `DeleteLink` method, look up the primary entity by the *key* parameter, find the related entity by the *relatedKey* parameter, and then remove the association. Depending on your data model, you might need to implement both versions of `DeleteLink`. Web API will call the correct version based on the request URI.

Supporting OData Actions in ASP.NET Web API 2

2/20/2020 • 6 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

In OData, *actions* are a way to add server-side behaviors that are not easily defined as CRUD operations on entities. Some uses for actions include:

- Implementing complex transactions.
- Manipulating several entities at once.
- Allowing updates only to certain properties of an entity.
- Sending information to the server that is not defined in an entity.

Software versions used in the tutorial

- Web API 2
- OData Version 3
- Entity Framework 6

Example: Rating a Product

In this example, we want to let users rate products, and then expose the average ratings for each product. On the database, we will store a list of ratings, keyed to products.

Here is the model we might use to represent the ratings in Entity Framework:

```
public class ProductRating
{
    public int ID { get; set; }

    [ForeignKey("Product")]
    public int ProductID { get; set; }
    public virtual Product Product { get; set; }  // Navigation property

    public int Rating { get; set; }
}
```

But we don't want clients to POST a `ProductRating` object to a "Ratings" collection. Intuitively, the rating is associated with the Products collection, and the client should only need to post the rating value.

Therefore, instead of using the normal CRUD operations, we define an action that a client can invoke on a Product. In OData terminology, the action is *bound* to Product entities.

Actions have side-effects on the server. For this reason, they are invoked using HTTP POST requests. Actions can have parameters and return types, which are described in the service metadata. The client sends the parameters in the request body, and the server sends the return value in the response body. To invoke the "Rate Product" action, the client sends a POST to a URI like the following:

```
http://localhost/odata/Products(1)/RateProduct
```

The data in the POST request is simply the product rating:

```
{"Rating":2}
```

Declare the Action in the Entity Data Model

In your Web API configuration, add the action to the entity data model (EDM):

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        ODataConventionModelBuilder builder = new ODataConventionModelBuilder();
        builder.EntitySet<Product>("Products");
        builder.EntitySet<Supplier>("Suppliers");
        builder.EntitySet<ProductRating>("Ratings");

        // New code: Add an action to the EDM, and define the parameter and return type.
        ActionConfiguration rateProduct = builder.Entity<Product>().Action("RateProduct");
        rateProduct.Parameter<int>("Rating");
        rateProduct.Returns<double>();

        config.Routes.MapODataRoute("odata", "odata", builder.GetEdmModel());
    }
}
```

This code defines "RateProduct" as an action that can be performed on Product entities. It also declares that the action takes an **int** parameter named "Rating", and returns an **int** value.

Add the Action to the Controller

The "RateProduct" action is bound to Product entities. To implement the action, add a method named `RateProduct` to the Products controller:

```
[HttpPost]
public async Task<IHttpActionResult> RateProduct([FromODataUri] int key, ODataActionParameters parameters)
{
    if (!ModelState.IsValid)
    {
        return BadRequest();
    }

    int rating = (int)parameters["Rating"];

    Product product = await db.Products.FindAsync(key);
    if (product == null)
    {
        return NotFound();
    }

    product.Ratings.Add(new ProductRating() { Rating = rating });
    db.SaveChanges();

    double average = product.Ratings.Average(x => x.Rating);

    return Ok(average);
}
```

Notice that the method name matches the name of the action in the EDM. The method has two parameters:

- *key*: The key for the product to rate.
- *parameters*: A dictionary of action parameter values.

If you are using the default routing conventions, the key parameter must be named "key". It is also important to include the **[FromOdataUri]** attribute, as shown. This attribute tells Web API to use OData syntax rules when it parses the key from the request URI.

Use the *parameters* dictionary to get the action parameters:

```
if (!ModelState.IsValid)
{
    return BadRequest();
}
int rating = (int)parameters["Rating"];
```

If the client sends the action parameters in the correct format, the value of **ModelState.IsValid** is true. In that case, you can use the **ODataActionParameters** dictionary to get the parameter values. In this example, the `RateProduct` action takes a single parameter named "Rating".

Action Metadata

To view the service metadata, send a GET request to /odata/$metadata. Here is the portion of the metadata that declares the `RateProduct` action:

```
<FunctionImport Name="RateProduct" m:IsAlwaysBindable="true" IsBindable="true" ReturnType="Edm.Double">
  <Parameter Name="bindingParameter" Type="ProductService.Models.Product"/>
  <Parameter Name="Rating" Nullable="false" Type="Edm.Int32"/>
</FunctionImport>
```

The **FunctionImport** element declares the action. Most of the fields are self-explanatory, but two are worth noting:

- **IsBindable** means the action can be invoked on the target entity, at least some of the time.

- **IsAlwaysBindable** means the action can always be invoked on the target entity.

The difference is that some actions are always available to clients, but other actions might depend on the state of the entity. For example, suppose you define a "Purchase" action. You can only purchase an item that is in stock. If the item is out of stock, a client cannot invoke that action.

When you define the EDM, the **Action** method creates an always-bindable action:

```
builder.Entity<Product>().Action("RateProduct"); // Always bindable
```

I'll talk about not-always-bindable actions (also called *transient* actions) later in this topic.

Invoking the Action

Now let's see how a client would invoke this action. Suppose the client wants to give a rating of 2 to the product with ID = 4. Here is an example request message, using JSON format for the request body:

```
POST http://localhost/odata/Products(4)/RateProduct HTTP/1.1
Content-Type: application/json
Content-Length: 12

{"Rating":2}
```

Here is the response message:

```
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
DataServiceVersion: 3.0
Date: Tue, 22 Oct 2013 19:04:00 GMT
Content-Length: 89

{
  "odata.metadata":"http://localhost:21900/odata/$metadata#Edm.Double","value":2.75
}
```

Binding an Action to an Entity Set

In the previous example, the action is bound to a single entity: The client rates a single product. You can also bind an action to a collection of entities. Just make the following changes:

In the EDM, add the action to the entity's **Collection** property.

```
var rateAllProducts = builder.Entity<Product>().Collection.Action("RateAllProducts");
```

In the controller method, omit the *key* parameter.

```
[HttpPost]
public int RateAllProducts(ODataActionParameters parameters)
{
    // ....
}
```

Now the client invokes the action on the Products entity set:

```
http://localhost/odata/Products/RateAllProducts
```

Actions with Collection Parameters

Actions can have parameters that take a collection of values. In the EDM, use **CollectionParameter<T>** to declare the parameter.

```
rateAllProducts.CollectionParameter<int>("Ratings");
```

This declares a parameter named "Ratings" that takes a collection of **int** values. In the controller method, you still get the parameter value from the **ODataActionParameters** object, but now the value is an **ICollection<int>** value:

```
[HttpPost]
public void RateAllProducts(ODataActionParameters parameters)
{
    if (!ModelState.IsValid)
    {
        throw new HttpResponseException(HttpStatusCode.BadRequest);
    }

    var ratings = parameters["Ratings"] as ICollection<int>;

    // ...
}
```

Transient Actions

In the "RateProduct" example, users can always rate a product, so the action is always available. But some actions depend on the state of the entity. For example, in a video rental service, the "CheckOut" action is not always available. (It depends whether a copy of that video is available.) This type of action is called a *transient* action.

In the service metadata, a transient action has **IsAlwaysBindable** equal to false. That's actually the default value, so the metadata will look like this:

```
<FunctionImport Name="CheckOut" IsBindable="true">
    <Parameter Name="bindingParameter" Type="ProductsService.Models.Product" />
</FunctionImport>
```

Here's why this matters: If an action is transient, the server needs to tell the client when the action is available. It does this by including a link to the action in the entity. Here is an example for a Movie entity:

```
{
  "odata.metadata":"http://localhost:17916/odata/$metadata#Movies/@Element",
  "#CheckOut":{ "target":"http://localhost:17916/odata/Movies(1)/CheckOut" },
  "ID":1,"Title":"Sudden Danger 3","Year":2012,"Genre":"Action"
}
```

The "#CheckOut" property contains a link to the CheckOut action. If the action is not available, the server omits the link.

To declare a transient action in the EDM, call the **TransientAction** method:

```
var checkoutAction = builder.Entity<Movie>().TransientAction("CheckOut");
```

Also, you must provide a function that returns an action link for a given entity. Set this function by calling **HasActionLink**. You can write the function as a lambda expression:

```
checkoutAction.HasActionLink(ctx =>
{
    var movie = ctx.EntityInstance as Movie;
    if (movie.IsAvailable) {
        return new Uri(ctx.Url.ODataLink(
            new EntitySetPathSegment(ctx.EntitySet),
            new KeyValuePathSegment(movie.ID.ToString()),
            new ActionPathSegment(checkoutAction.Name)));
    }
    else
    {
        return null;
    }
}, followsConventions: true);
```

If the action is available, the lambda expression returns a link to the action. The OData serializer includes this link when it serializes the entity. When the action is not available, the function returns `null`.

OData Actions Sample

Calling an OData Service From a .NET Client (C#)

2/20/2020 • 8 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

> This tutorial shows how to call an OData service from a C# client application.
>
> ## Software versions used in the tutorial
>
> - Visual Studio 2013 (works with Visual Studio 2012)
> - WCF Data Services Client Library
> - Web API 2. (The example OData service is built using Web API 2, but the client application does not depend on Web API.)

In this tutorial, I'll walk through creating a client application that calls an OData service. The OData service exposes the following entities:

- `Product`
- `Supplier`
- `ProductRating`

The following articles describe how to implement the OData service in Web API. (You don't need to read them to understand this tutorial, however.)

- Creating an OData Endpoint in Web API 2
- OData Entity Relations in Web API 2
- OData Actions in Web API 2

Generate the Service Proxy

The first step is to generate a service proxy. The service proxy is a .NET class that defines methods for accessing

the OData service. The proxy translates method calls into HTTP requests.

Start by opening the OData service project in Visual Studio. Press CTRL+F5 to run the service locally in IIS Express. Note the local address, including the port number that Visual Studio assigns. You will need this address when you create the proxy.

Next, open another instance of Visual Studio and create a console application project. The console application will be our OData client application. (You can also add the project to the same solution as the service.)

> **NOTE**
>
> The remaining steps refer the console project.

In Solution Explorer, right-click **References** and select **Add Service Reference**.

In the **Add Service Reference** dialog, type the address of the OData service:

```
http://localhost:port/odata
```

where *port* is the port number.

For **Namespace**, type "ProductService". This option defines the namespace of the proxy class.

Click **Go**. Visual Studio reads the OData metadata document to discover the entities in the service.

Click **OK** to add the proxy class to your project.

Create an Instance of the Service Proxy Class

Inside your `Main` method, create a new instance of the proxy class, as follows:

```
using System;
using System.Data.Services.Client;
using System.Linq;

namespace Client
{
    class Program
    {
        static void Main(string[] args)
        {
            Uri uri = new Uri("http://localhost:1234/odata/");
            var container = new ProductService.Container(uri);

            // ...
        }
    }
}
```

Again, use the actual port number where your service is running. When you deploy your service, you will use the URI of the live service. You don't need to update the proxy.

The following code adds an event handler that prints the request URIs to the console window. This step isn't required, but it's interesting to see the URIs for each query.

```
container.SendingRequest2 += (s, e) =>
{
    Console.WriteLine("{0} {1}", e.RequestMessage.Method, e.RequestMessage.Url);
};
```

Query the Service

The following code gets the list of products from the OData service.

```
class Program
{
    static void DisplayProduct(ProductService.Product product)
    {
        Console.WriteLine("{0} {1} {2}", product.Name, product.Price, product.Category);
    }

    // Get an entire entity set.
    static void ListAllProducts(ProductService.Container container)
    {
        foreach (var p in container.Products)
        {
            DisplayProduct(p);
        }
    }

    static void Main(string[] args)
    {
        Uri uri = new Uri("http://localhost:18285/odata/");
        var container = new ProductService.Container(uri);
        container.SendingRequest2 += (s, e) =>
        {
            Console.WriteLine("{0} {1}", e.RequestMessage.Method, e.RequestMessage.Url);
        };

        // Get the list of products
        ListAllProducts(container);
    }
}
```

Notice that you don't need to write any code to send the HTTP request or parse the response. The proxy class does this automatically when you enumerate the `Container.Products` collection in the **foreach** loop.

When you run the application, the output should look like the following:

```
GET http://localhost:60868/odata/Products
Hat 15.00   Apparel
Scarf   12.00   Apparel
Socks   5.00    Apparel
Yo-yo   4.95    Toys
Puzzle  8.00    Toys
```

To get an entity by ID, use a `where` clause.

```
// Get a single entity.
static void ListProductById(ProductService.Container container, int id)
{
    var product = container.Products.Where(p => p.ID == id).SingleOrDefault();
    if (product != null)
    {
        DisplayProduct(product);
    }
}
```

For the rest of this topic, I won't show the entire `Main` function, just the code needed to call the service.

Apply Query Options

OData defines query options that can be used to filter, sort, page data, and so forth. In the service proxy, you can apply these options by using various LINQ expressions.

In this section, I'll show brief examples. For more details, see the topic LINQ Considerations (WCF Data Services) on MSDN.

Filtering ($filter)

To filter, use a `where` clause. The following example filters by product category.

```
// Use the $filter option.
static void ListProductsInCategory(ProductService.Container container, string category)
{
    var products =
        from p in container.Products
        where p.Category == category
        select p;
    foreach (var p in products)
    {
        DisplayProduct(p);
    }
}
```

This code corresponds to the following OData query.

```
GET http://localhost/odata/Products()?$filter=Category eq 'apparel'
```

Notice that the proxy converts the `where` clause into an OData `$filter` expression.

Sorting ($orderby)

To sort, use an `orderby` clause. The following example sorts by price, from highest to lowest.

```
// Use the $orderby option
static void ListProductsSorted(ProductService.Container container)
{
    // Sort by price, highest to lowest.
    var products =
        from p in container.Products
        orderby p.Price descending
        select p;

    foreach (var p in products)
    {
        DisplayProduct(p);
    }
}
```

Here is the corresponding OData request.

```
GET http://localhost/odata/Products()?$orderby=Price desc
```

Client-Side Paging ($skip and $top)

For large entity sets, the client might want to limit the number of results. For example, a client might show 10 entries at a time. This is called *client-side paging*. (There is also server-side paging, where the server limits the number of results.) To perform client-side paging, use the LINQ **Skip** and **Take** methods. The following example skips the first 40 results and takes the next 10.

```
// Use $skip and $top options.
static void ListProductsPaged(ProductService.Container container)
{
    var products =
        (from p in container.Products
          orderby p.Price descending
          select p).Skip(40).Take(10);

    foreach (var p in products)
    {
        DisplayProduct(p);
    }
}
```

Here is the corresponding OData request:

```
GET http://localhost/odata/Products()?$orderby=Price desc&$skip=40&$top=10
```

Select ($select) and Expand ($expand)

To include related entities, use the `DataServiceQuery<t>.Expand` method. For example, to include the `Supplier` for each `Product`:

```
// Use the $expand option.
static void ListProductsAndSupplier(ProductService.Container container)
{
    var products = container.Products.Expand(p => p.Supplier);
    foreach (var p in products)
    {
        Console.WriteLine("{0}\t{1}\t{2}", p.Name, p.Price, p.Supplier.Name);
    }
}
```

Here is the corresponding OData request:

```
GET http://localhost/odata/Products()?$expand=Supplier
```

To change the shape of the response, use the LINQ **select** clause. The following example gets just the name of each product, with no other properties.

```
// Use the $select option.
static void ListProductNames(ProductService.Container container)
{

    var products = from p in container.Products select new { Name = p.Name };
    foreach (var p in products)
    {
        Console.WriteLine(p.Name);
    }
}
```

Here is the corresponding OData request:

```
GET http://localhost/odata/Products()?$select=Name
```

A select clause can include related entities. In that case, do not call **Expand**; the proxy automatically includes the expansion in this case. The following example gets the name and supplier of each product.

```
// Use $expand and $select options
static void ListProductNameSupplier(ProductService.Container container)
{
    var products =
        from p in container.Products
        select new
        {
            Name = p.Name,
            Supplier = p.Supplier.Name
        };
    foreach (var p in products)
    {
        Console.WriteLine("{0}\t{1}", p.Name, p.Supplier);
    }
}
```

Here is the corresponding OData request. Notice that it includes the **$expand** option.

```
GET http://localhost/odata/Products()?$expand=Supplier&$select=Name,Supplier/Name
```

For more information about $select and $expand, see Using $select, $expand, and $value in Web API 2.

Add a New Entity

To add a new entity to an entity set, call `AddToEntitySet`, where *EntitySet* is the name of the entity set. For example, `AddToProducts` adds a new `Product` to the `Products` entity set. When you generate the proxy, WCF Data Services automatically creates these strongly-typed **AddTo** methods.

```
// Add an entity.
static void AddProduct(ProductService.Container container, ProductService.Product product)
{
    container.AddToProducts(product);
    var serviceResponse = container.SaveChanges();
    foreach (var operationResponse in serviceResponse)
    {
        Console.WriteLine(operationResponse.StatusCode);
    }
}
```

To add a link between two entities, use the **AddLink** and **SetLink** methods. The following code adds a new supplier and a new product, and then creates links between them.

```
// Add entities with links.
static void AddProductWithSupplier(ProductService.Container container,
    ProductService.Product product, ProductService.Supplier supplier)
{
    container.AddToSuppliers(supplier);
    container.AddToProducts(product);
    container.AddLink(supplier, "Products", product);
    container.SetLink(product, "Supplier", supplier);
    var serviceResponse = container.SaveChanges();
    foreach (var operationResponse in serviceResponse)
    {
        Console.WriteLine(operationResponse.StatusCode);
    }
}
```

Use **AddLink** when the navigation property is a collection. In this example, we are adding a product to the `Products` collection on the supplier.

Use **SetLink** when the navigation property is a single entity. In this example, we are setting the `Supplier` property on the product.

Update / Patch

To update an entity, call the **UpdateObject** method.

```
static void UpdatePrice(ProductService.Container container, int id, decimal price)
{
    var product = container.Products.Where(p => p.ID == id).SingleOrDefault();
    if (product != null)
    {
        product.Price = price;
        container.UpdateObject(product);
        container.SaveChanges(SaveChangesOptions.PatchOnUpdate);
    }
}
```

The update is performed when you call **SaveChanges**. By default, WCF sends an HTTP MERGE request. The **PatchOnUpdate** option tells WCF to send an HTTP PATCH instead.

> **NOTE**
> Why PATCH versus MERGE? The original HTTP 1.1 specification (RCF 2616) did not define any HTTP method with "partial update" semantics. To support partial updates, the OData specification defined the MERGE method. In 2010, RFC 5789 defined the PATCH method for partial updates. You can read some of the history in this blog post on the WCF Data Services Blog. Today, PATCH is preferred over MERGE. The OData controller created by the Web API scaffolding supports both methods.

If you want to replace the entire entity (PUT semantics), specify the **ReplaceOnUpdate** option. This causes WCF to send an HTTP PUT request.

```
container.SaveChanges(SaveChangesOptions.ReplaceOnUpdate);
```

Delete an Entity

To delete an entity, call **DeleteObject**.

```
static void DeleteProduct(ProductService.Container container, int id)
{
    var product = container.Products.Where(p => p.ID == id).SingleOrDefault();
    if (product != null)
    {
        container.DeleteObject(product);
        container.SaveChanges();
    }
}
```

Invoke an OData Action

In OData, actions are a way to add server-side behaviors that are not easily defined as CRUD operations on entities.

Although the OData metadata document describes the actions, the proxy class does not create any strongly-typed methods for them. You can still invoke an OData action by using the generic **Execute** method. However, you will

need to know the data types of the parameters and the return value.

For example, the `RateProduct` action takes parameter named "Rating" of type `Int32` and returns a `double`. The following code shows how to invoke this action.

```
int rating = 2;
Uri actionUri = new Uri(uri, "Products(5)/RateProduct");
var averageRating = container.Execute<double>(
    actionUri, "POST", true, new BodyOperationParameter("Rating", rating)).First();
```

For more information, see Calling Service Operations and Actions.

One option is to extend the **Container** class to provide a strongly typed method that invokes the action:

```
namespace ProductServiceClient.ProductService
{
    public partial class Container
    {
        public double RateProduct(int productID, int rating)
        {
            Uri actionUri = new Uri(this.BaseUri,
                String.Format("Products({0})/RateProduct", productID)
                );

            return this.Execute<double>(actionUri,
                "POST", true, new BodyOperationParameter("Rating", rating)).First();
        }
    }
}
```

Supporting OData Query Options in ASP.NET Web API 2

2/20/2020 • 6 minutes to read • Edit Online

by Mike Wasson

This overview with code examples demonstrates the supporting OData Query Options in ASP.NET Web API 2 for ASP.NET 4.x.

OData defines parameters that can be used to modify an OData query. The client sends these parameters in the query string of the request URI. For example, to sort the results, a client uses the $orderby parameter:

```
http://localhost/Products?$orderby=Name
```

The OData specification calls these parameters *query options*. You can enable OData query options for any Web API controller in your project — the controller does not need to be an OData endpoint. This gives you a convenient way to add features such as filtering and sorting to any Web API application.

Before enabling query options, please read the topic OData Security Guidance.

- Enabling OData Query Options
- Example Queries
- Server-Driven Paging
- Limiting the Query Options
- Invoking Query Options Directly
- Query Validation

Enabling OData Query Options

Web API supports the following OData query options:

OPTION	DESCRIPTION
$expand	Expands related entities inline.
$filter	Filters the results, based on a Boolean condition.
$inlinecount	Tells the server to include the total count of matching entities in the response. (Useful for server-side paging.)
$orderby	Sorts the results.
$select	Selects which properties to include in the response.
$skip	Skips the first n results.
$top	Returns only the first n the results.

To use OData query options, you must enable them explicitly. You can enable them globally for the entire application, or enable them for specific controllers or specific actions.

To enable OData query options globally, call **EnableQuerySupport** on the **HttpConfiguration** class at startup:

```
public static void Register(HttpConfiguration config)
{
    // ...

    config.EnableQuerySupport();

    // ...
}
```

The **EnableQuerySupport** method enables query options globally for any controller action that returns an **IQueryable** type. If you don't want query options enabled for the entire application, you can enable them for specific controller actions by adding the **[Queryable]** attribute to the action method.

```
public class ProductsController : ApiController
{
    [Queryable]
    IQueryable<Product> Get() {}
}
```

Example Queries

This section shows the types of queries that are possible using the OData query options. For specific details about the query options, refer to the OData documentation at www.odata.org.

For information about $expand and $select, see Using $select, $expand, and $value in ASP.NET Web API OData.

Client-Driven Paging

For large entity sets, the client might want to limit the number of results. For example, a client might show 10 entries at a time, with "next" links to get the next page of results. To do this, the client uses the $top and $skip options.

`http://localhost/Products?$top=10&$skip=20`

The $top option gives the maximum number of entries to return, and the $skip option gives the number of entries to skip. The previous example fetches entries 21 through 30.

Filtering

The $filter option lets a client filter the results by applying a Boolean expression. The filter expressions are quite powerful; they include logical and arithmetic operators, string functions, and date functions.

RETURN ALL PRODUCTS WITH CATEGORY EQUAL TO "TOYS".	`HTTP://LOCALHOST/PRODUCTS?$FILTER=CATEGORY` EQ 'TOYS'
Return all products with price less than 10.	`http://localhost/Products?$filter=Price` lt 10
Logical operators: Return all products where price >= 5 and price <= 15.	`http://localhost/Products?$filter=Price` ge 5 and Price le 15
String functions: Return all products with "zz" in the name.	`http://localhost/Products?$filter=substringof('zz',Name)`
Date functions: Return all products with ReleaseDate after 2005.	`http://localhost/Products?$filter=year(ReleaseDate)` gt 2005

Sorting

To sort the results, use the $orderby filter.

SORT BY PRICE.	`HTTP://LOCALHOST/PRODUCTS?$ORDERBY=PRICE`
Sort by price in descending order (highest to lowest).	`http://localhost/Products?$orderby=Price desc`
Sort by category, then sort by price in descending order within categories.	`http://localhost/odata/Products?$orderby=Category,Price desc`

Server-Driven Paging

If your database contains millions of records, you don't want to send them all in one payload. To prevent this, the server can limit the number of entries that it sends in a single response. To enable server paging, set the **PageSize** property in the **Queryable** attribute. The value is the maximum number of entries to return.

```
[Queryable(PageSize=10)]
public IQueryable<Product> Get()
{
    return products.AsQueryable();
}
```

If your controller returns OData format, the response body will contain a link to the next page of data:

```
{
  "odata.metadata":"http://localhost/$metadata#Products",
  "value":[
    { "ID":1,"Name":"Hat","Price":"15","Category":"Apparel" },
    { "ID":2,"Name":"Socks","Price":"5","Category":"Apparel" },
    // Others not shown
  ],
  "odata.nextLink":"http://localhost/Products?$skip=10"
}
```

The client can use this link to fetch the next page. To learn the total number of entries in the result set, the client can set the $inlinecount query option with the value "allpages".

`http://localhost/Products?$inlinecount=allpages`

The value "allpages" tells the server to include the total count in the response:

```
{
  "odata.metadata":"http://localhost/$metadata#Products",
  "odata.count":"50",
  "value":[
    { "ID":1,"Name":"Hat","Price":"15","Category":"Apparel" },
    { "ID":2,"Name":"Socks","Price":"5","Category":"Apparel" },
    // Others not shown
  ]
}
```

NOTE

Next-page links and inline count both require OData format. The reason is that OData defines special fields in the response body to hold the link and count.

For non-OData formats, it is still possible to support next-page links and inline count, by wrapping the query results in a **PageResult<T>** object. However, it requires a bit more code. Here is an example:

```
public PageResult<Product> Get(ODataQueryOptions<Product> options)
{
    ODataQuerySettings settings = new ODataQuerySettings()
    {
        PageSize = 5
    };

    IQueryable results = options.ApplyTo(_products.AsQueryable(), settings);

    return new PageResult<Product>(
        results as IEnumerable<Product>,
        Request.GetNextPageLink(),
        Request.GetInlineCount());
}
```

Here is an example JSON response:

```
{
  "Items": [
    { "ID":1,"Name":"Hat","Price":"15","Category":"Apparel" },
    { "ID":2,"Name":"Socks","Price":"5","Category":"Apparel" },

    // Others not shown

  ],
  "NextPageLink": "http://localhost/api/values?$inlinecount=allpages&$skip=10",
  "Count": 50
}
```

Limiting the Query Options

The query options give the client a lot of control over the query that is run on the server. In some cases, you might want to limit the available options for security or performance reasons. The **[Queryable]** attribute has some built in properties for this. Here are some examples.

Allow only $skip and $top, to support paging and nothing else:

```
[Queryable(AllowedQueryOptions=
    AllowedQueryOptions.Skip | AllowedQueryOptions.Top)]
```

Allow ordering only by certain properties, to prevent sorting on properties that are not indexed in the database:

```
[Queryable(AllowedOrderByProperties="Id")] // comma-separated list of properties
```

Allow the "eq" logical function but no other logical functions:

```
[Queryable(AllowedLogicalOperators=AllowedLogicalOperators.Equal)]
```

Do not allow any arithmetic operators:

```
[Queryable(AllowedArithmeticOperators=AllowedArithmeticOperators.None)]
```

You can restrict options globally by constructing a **QueryableAttribute** instance and passing it to the **EnableQuerySupport** function:

```
var queryAttribute = new QueryableAttribute()
{
    AllowedQueryOptions = AllowedQueryOptions.Top | AllowedQueryOptions.Skip,
    MaxTop = 100
};

config.EnableQuerySupport(queryAttribute);
```

Invoking Query Options Directly

Instead of using the **[Queryable]** attribute, you can invoke the query options directly in your controller. To do so, add an **ODataQueryOptions** parameter to the controller method. In this case, you don't need the **[Queryable]** attribute.

```
public IQueryable<Product> Get(ODataQueryOptions opts)
{
    var settings = new ODataValidationSettings()
    {
        // Initialize settings as needed.
        AllowedFunctions = AllowedFunctions.AllMathFunctions
    };

    opts.Validate(settings);

    IQueryable results = opts.ApplyTo(products.AsQueryable());
    return results as IQueryable<Product>;
}
```

Web API populates the **ODataQueryOptions** from the URI query string. To apply the query, pass an **IQueryable** to the **ApplyTo** method. The method returns another **IQueryable**.

For advanced scenarios, if you do not have an **IQueryable** query provider, you can examine the **ODataQueryOptions** and translate the query options into another form. (For example, see RaghuRam Nadiminti's blog post Translating OData queries to HQL, which also includes a sample.)

Query Validation

The **[Queryable]** attribute validates the query before executing it. The validation step is performed in the **QueryableAttribute.ValidateQuery** method. You can also customize the validation process.

Also see OData Security Guidance.

First, override one of the validator classes that is defined in the **Web.Http.OData.Query.Validators** namespace. For example, the following validator class disables the 'desc' option for the $orderby option.

```
public class MyOrderByValidator : OrderByQueryValidator
{
    // Disallow the 'desc' parameter for $orderby option.
    public override void Validate(OrderByQueryOption orderByOption,
                                  ODataValidationSettings validationSettings)
    {
        if (orderByOption.OrderByNodes.Any(
                node => node.Direction == OrderByDirection.Descending))
        {
            throw new ODataException("The 'desc' option is not supported.");
        }
        base.Validate(orderByOption, validationSettings);
    }
}
```

Subclass the **[Queryable]** attribute to override the **ValidateQuery** method.

```
public class MyQueryableAttribute : QueryableAttribute
{
    public override void ValidateQuery(HttpRequestMessage request,
        ODataQueryOptions queryOptions)
    {
        if (queryOptions.OrderBy != null)
        {
            queryOptions.OrderBy.Validator = new MyOrderByValidator();
        }
        base.ValidateQuery(request, queryOptions);
    }
}
```

Then set your custom attribute either globally or per-controller:

```
// Globally:
config.EnableQuerySupport(new MyQueryableAttribute());

// Per controller:
public class ValuesController : ApiController
{
    [MyQueryable]
    public IQueryable<Product> Get()
    {
        return products.AsQueryable();
    }
}
```

If you are using **ODataQueryOptions** directly, set the validator on the options:

```
public IQueryable<Product> Get(ODataQueryOptions opts)
{
    if (opts.OrderBy != null)
    {
        opts.OrderBy.Validator = new MyOrderByValidator();
    }

    var settings = new ODataValidationSettings()
    {
        // Initialize settings as needed.
        AllowedFunctions = AllowedFunctions.AllMathFunctions
    };

    // Validate
    opts.Validate(settings);

    IQueryable results = opts.ApplyTo(products.AsQueryable());
    return results as IQueryable<Product>;
}
```

Using $select, $expand, and $value in ASP.NET Web API 2 OData

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

Overview and code samples for the $expand, $select, and $value options in OData Web API 2 for ASP.NET 4.x. These options allow a client to control the representation that it gets back from the server.

- **$expand** causes related entities to be included inline in the response.
- **$select** selects a subset of properties to include in the response.
- **$value** gets the raw value of a property.

Example Schema

For this article, I'll use an OData service that defines three entities: Product, Supplier, and Category. Each product has one category and one supplier.

Here are the C# classes that define the entity models:

```
public class Supplier
{
    [Key]
    public string Key {get; set; }
    public string Name { get; set; }
}
public class Category
{
    public int ID { get; set; }
    public string Name { get; set; }
    public virtual ICollection<Product> Products { get; set; }
}

public class Product
{
    public int ID { get; set; }
    public string Name { get; set; }
    public decimal Price { get; set; }

    [ForeignKey("Category")]
    public int CategoryId { get; set; }
    public Category Category { get; set; }

    [ForeignKey("Supplier")]
    public string SupplierId { get; set; }
    public virtual Supplier Supplier { get; set; }
}
```

Notice that the `Product` class defines navigation properties for the `Supplier` and `Category`. The `Category` class defines a navigation property for the products in each category.

To create an OData endpoint for this schema, use the Visual Studio 2013 scaffolding, as described in Creating an OData Endpoint in ASP.NET Web API. Add separate controllers for Product, Category, and Supplier.

Enabling $expand and $select

In Visual Studio 2013, the Web API OData scaffolding creates a controller that automatically supports $expand and $select. For reference, here are the requirements to support $expand and $select in a controller.

For collections, the controller's `Get` method must return an **IQueryable**.

```
[Queryable]
public IQueryable<Category> GetCategories()
{
    return db.Categories;
}
```

For single entities, return a **SingleResult<T>**, where T is an **IQueryable** that contains zero or one entities.

```
[Queryable]
public SingleResult<Category> GetCategory([FromODataUri] int key)
{
    return SingleResult.Create(db.Categories.Where(c => c.ID == key));
}
```

Also, decorate your `Get` methods with the **[Queryable]** attribute, as shown in the previous code snippets. Alternatively, call **EnableQuerySupport** on the **HttpConfiguration** object at startup. (For more information, see Enabling OData Query Options.)

Using $expand

When you query an OData entity or collection, the default response does not include related entities. For example, here is the default response for the Categories entity set:

```
{
  "odata.metadata":"http://localhost/odata/$metadata#Categories",
  "value":[
    {"ID":1,"Name":"Apparel"},
    {"ID":2,"Name":"Toys"}
  ]
}
```

As you can see, the response does not include any products, even though the Category entity has a Products navigation link. However, the client can use $expand to get the list of products for each category. The $expand option goes in the query string of the request:

```
GET http://localhost/odata/Categories?$expand=Products
```

Now the server will include the products for each category, inline with the categories. Here is the response payload:

```
{
  "odata.metadata":"http://localhost/odata/$metadata#Categories",
  "value":[
    {
      "Products":[
        {"ID":1,"Name":"Hat","Price":"15.00","CategoryId":1,"SupplierId":"CTSO"},
        {"ID":2,"Name":"Scarf","Price":"12.00","CategoryId":1,"SupplierId":"CTSO"},
        {"ID":3,"Name":"Socks","Price":"5.00","CategoryId":1,"SupplierId":"FBRK"}
      ],
      "ID":1,
      "Name":"Apparel"
    },
    {
      "Products":[
        {"ID":4,"Name":"Yo-yo","Price":"4.95","CategoryId":2,"SupplierId":"WING"},
        {"ID":5,"Name":"Puzzle","Price":"8.00","CategoryId":2,"SupplierId":"WING"}
      ],
      "ID":2,
      "Name":"Toys"
    }
  ]
}
```

Notice that each entry in the "value" array contains a Products list.

The $expand option takes a comma-separated list of navigation properties to expand. The following request expands both the category and the supplier for a product.

```
GET http://localhost/odata/Products(1)?$expand=Category,Supplier
```

Here is the response body:

```
{
  "odata.metadata":"http://localhost/odata/$metadata#Products/@Element",
  "Category": {"ID":1,"Name":"Apparel"},
  "Supplier":{"Key":"CTSO","Name":"Contoso, Ltd."},
  "ID":1,
  "Name":"Hat",
  "Price":"15.00",
  "CategoryId":1,
  "SupplierId":"CTSO"
}
```

You can expand more than one level of navigation property. The following example includes all the products for a category and also the supplier for each product.

```
GET http://localhost/odata/Categories(1)?$expand=Products/Supplier
```

Here is the response body:

```
{
  "odata.metadata":"http://localhost/odata/$metadata#Categories/@Element",
  "Products":[
    {
      "Supplier":{"Key":"CTSO","Name":"Contoso, Ltd."},
      "ID":1,"Name":"Hat","Price":"15.00","CategoryId":1,"SupplierId":"CTSO"
    },
    {
      "Supplier":{"Key":"CTSO","Name":"Contoso, Ltd."},
      "ID":2,"Name":"Scarf","Price":"12.00","CategoryId":1,"SupplierId":"CTSO"
    },{
      "Supplier":{
        "Key":"FBRK","Name":"Fabrikam, Inc."
      },"ID":3,"Name":"Socks","Price":"5.00","CategoryId":1,"SupplierId":"FBRK"
    }
  ],"ID":1,"Name":"Apparel"
}
```

By default, Web API limits the maximum expansion depth to 2. That prevents the client from sending complex requests like `$expand=Orders/OrderDetails/Product/Supplier/Region`, which might be inefficient to query and create large responses. To override the default, set the **MaxExpansionDepth** property on the **[Queryable]** attribute.

```
[Queryable(MaxExpansionDepth=4)]
public IQueryable<Category> GetCategories()
{
    return db.Categories;
}
```

For more information about the $expand option, see Expand System Query Option ($expand) in the official OData documentation.

Using $select

The $select option specifies a subset of properties to include in the response body. For example, to get only the name and price of each product, use the following query:

```
GET http://localhost/odata/Products?$select=Price,Name
```

Here is the response body:

```
{
  "odata.metadata":"http://localhost/odata/$metadata#Products&$select=Price,Name",
  "value":[
    {"Price":"15.00","Name":"Hat"},
    {"Price":"12.00","Name":"Scarf"},
    {"Price":"5.00","Name":"Socks"},
    {"Price":"4.95","Name":"Yo-yo"},
    {"Price":"8.00","Name":"Puzzle"}
  ]
}
```

You can combine $select and $expand in the same query. Make sure to include the expanded property in the $select option. For example, the following request gets the product name and supplier.

```
GET http://localhost/odata/Products?$select=Name,Supplier&$expand=Supplier
```

Here is the response body:

```
{
  "odata.metadata":"http://localhost/odata/$metadata#Products&$select=Name,Supplier",
  "value":[
    {
      "Supplier":{"Key":"CTSO","Name":"Contoso, Ltd."},
      "Name":"Hat"
    },
    {
      "Supplier":{"Key":"CTSO","Name":"Contoso, Ltd."},
      "Name":"Scarf"
    },
    {
      "Supplier":{"Key":"FBRK","Name":"Fabrikam, Inc."},
      "Name":"Socks"
    },
    {
      "Supplier":{"Key":"WING","Name":"Wingtip Toys"},
      "Name":"Yo-yo"
    },
    {
      "Supplier":{"Key":"WING","Name":"Wingtip Toys"},
      "Name":"Puzzle"
   }
  ]
}
```

You can also select the properties within an expanded property. The following request expands Products and selects category name plus product name.

```
GET http://localhost/odata/Categories?$expand=Products&$select=Name,Products/Name
```

Here is the response body:

```
{
  "odata.metadata":"http://localhost/odata/$metadata#Categories&$select=Name,Products/Name",
  "value":[
    {
      "Products":[ {"Name":"Hat"},{"Name":"Scarf"},{"Name":"Socks"} ],
      "Name":"Apparel"
    },
    {
      "Products":[ {"Name":"Yo-yo"},{"Name":"Puzzle"} ],
      "Name":"Toys"
    }
  ]
}
```

For more information about the $select option, see Select System Query Option ($select) in the official OData documentation.

Getting Individual Properties of an Entity ($value)

There are two ways for an OData client to get an individual property from an entity. The client can either get the value in OData format, or get the raw value of the property.

The following request gets a property in OData format.

```
GET http://localhost/odata/Products(1)/Name
```

Here is an example response in JSON format:

```
HTTP/1.1 200 OK
Content-Type: application/json; odata=minimalmetadata; streaming=true; charset=utf-8
DataServiceVersion: 3.0
Content-Length: 90

{
  "odata.metadata":"http://localhost:14239/odata/$metadata#Edm.String",
  "value":"Hat"
}
```

To get the raw value of the property, append $value to the URI:

```
GET http://localhost/odata/Products(1)/Name/$value
```

Here is the response. Notice that the content type is "text/plain", not JSON.

```
HTTP/1.1 200 OK
Content-Type: text/plain; charset=utf-8
DataServiceVersion: 3.0
Content-Length: 3

Hat
```

To support these queries in your OData controller, add a method named `GetProperty`, where `Property` is the name of the property. For example, the method to get the Name property would be named `GetName`. The method should return the value of that property:

```
public async Task<IHttpActionResult> GetName(int key)
{
    Product product = await db.Products.FindAsync(key);
    if (product == null)
    {
        return NotFound();
    }
    return Ok(product.Name);
}
```

Routing Conventions in ASP.NET Web API 2 Odata

2/20/2020 • 7 minutes to read • Edit Online

by Mike Wasson

> This article describes the routing conventions that Web API 2 in ASP.NET 4.x uses for OData endpoints.

When Web API gets an OData request, it maps the request to a controller name and an action name. The mapping is based on the HTTP method and the URI. For example, `GET /odata/Products(1)` maps to `ProductsController.GetProduct`.

In part 1 of this article, I describe the built-in OData routing conventions. These conventions are designed specifically for OData endpoints, and they replace the default Web API routing system. (The replacement happens when you call **MapODataRoute**.)

In part 2, I show how to add custom routing conventions. Currently the built-in conventions do not cover the entire range of OData URIs, but you can extend them to handle additional cases.

- Built-in Routing Conventions
- Custom Routing Conventions

Built-in Routing Conventions

Before I describe the OData routing conventions in Web API, it's helpful to understand OData URIs. An OData URI consists of:

- The service root
- The resource path
- Query options

http://example.com/odata	/Products(1)/Supplier	?$top=2
Service root	Resource path	Query options

For routing, the important part is the resource path. The resource path is divided into segments. For example, `/Products(1)/Supplier` has three segments:

- `Products` refers to an entity set named "Products".
- `1` is an entity key, selecting a single entity from the set.
- `Supplier` is a navigation property that selects a related entity.

So this path picks out the supplier of product 1.

> **NOTE**
>
> OData path segments do not always correspond to URI segments. For example, "1" is considered a path segment.

Controller Names. The controller name is always derived from the entity set at the root of the resource path. For example, if the resource path is `/Products(1)/Supplier`, Web API looks for a controller named `ProductsController`.

Action Names. Action names are derived from the path segments plus the entity data model (EDM), as listed in the following tables. In some cases, you have two choices for the action name. For example, "Get" or

"GetProducts".

Querying Entities

REQUEST	EXAMPLE URI	ACTION NAME	EXAMPLE ACTION
GET /entityset	/Products	GetEntitySet or Get	GetProducts
GET /entityset(key)	/Products(1)	GetEntityType or Get	GetProduct
GET /entityset(key)/cast	/Products(1)/Models.Book	GetEntityType or Get	GetBook

For more information, see Create a Read-Only OData Endpoint.

Creating, Updating, and Deleting Entities

REQUEST	EXAMPLE URI	ACTION NAME	EXAMPLE ACTION
POST /entityset	/Products	PostEntityType or Post	PostProduct
PUT /entityset(key)	/Products(1)	PutEntityType or Put	PutProduct
PUT /entityset(key)/cast	/Products(1)/Models.Book	PutEntityType or Put	PutBook
PATCH /entityset(key)	/Products(1)	PatchEntityType or Patch	PatchProduct
PATCH /entityset(key)/cast	/Products(1)/Models.Book	PatchEntityType or Patch	PatchBook
DELETE /entityset(key)	/Products(1)	DeleteEntityType or Delete	DeleteProduct
DELETE /entityset(key)/cast	/Products(1)/Models.Book	DeleteEntityType or Delete	DeleteBook

Querying a Navigation Property

REQUEST	EXAMPLE URI	ACTION NAME	EXAMPLE ACTION
GET /entityset(key)/navigation	/Products(1)/Supplier	GetNavigationFromEntityType or GetNavigation	GetSupplierFromProduct
GET /entityset(key)/cast/navigation	/Products(1)/Models.Book/Author	GetNavigationFromEntityType or GetNavigation	GetAuthorFromBook

For more information, see Working with Entity Relations.

Creating and Deleting Links

REQUEST	EXAMPLE URI	ACTION NAME
POST /entityset(key)/$links/navigation	/Products(1)/$links/Supplier	CreateLink
PUT /entityset(key)/$links/navigation	/Products(1)/$links/Supplier	CreateLink
DELETE /entityset(key)/$links/navigation	/Products(1)/$links/Supplier	DeleteLink

REQUEST	EXAMPLE URI	ACTION NAME
DELETE /entityset(key)/$links/navigation(relatedKey)	/Products/(1)/$links/Suppliers(1)	DeleteLink

For more information, see Working with Entity Relations.

Properties

Requires Web API 2

REQUEST	EXAMPLE URI	ACTION NAME	EXAMPLE ACTION
GET /entityset(key)/property	/Products(1)/Name	GetPropertyFromEntityType or GetProperty	GetNameFromProduct
GET /entityset(key)/cast/property	/Products(1)/Models.Book/Author	GetPropertyFromEntityType or GetProperty	GetTitleFromBook

Actions

REQUEST	EXAMPLE URI	ACTION NAME	EXAMPLE ACTION
POST /entityset(key)/action	/Products(1)/Rate	ActionNameOnEntityType or ActionName	RateOnProduct
POST /entityset(key)/cast/action	/Products(1)/Models.Book/CheckOut	ActionNameOnEntityType or ActionName	CheckOutOnBook

For more information, see OData Actions.

Method Signatures

Here are some rules for the method signatures:

- If the path contains a key, the action should have a parameter named *key*.
- If the path contains a key into a navigation property, the action should have a parameter named *relatedKey*.
- Decorate *key* and *relatedKey* parameters with the **[FromODataUri]** parameter.
- POST and PUT requests take a parameter of the entity type.
- PATCH requests take a parameter of type **Delta<T>**, where *T* is the entity type.

For reference, here is an example that shows method signatures for every built-in OData routing convention.

```
public class ProductsController : ODataController
{
    // GET /odata/Products
    public IQueryable<Product> Get()

    // GET /odata/Products(1)
    public Product Get([FromODataUri] int key)

    // GET /odata/Products(1)/ODataRouting.Models.Book
    public Book GetBook([FromODataUri] int key)

    // POST /odata/Products
    public HttpResponseMessage Post(Product item)

    // PUT /odata/Products(1)
    public HttpResponseMessage Put([FromODataUri] int key, Product item)

    // PATCH /odata/Products(1)
    public HttpResponseMessage Patch([FromODataUri] int key, Delta<Product> item)

    // DELETE /odata/Products(1)
    public HttpResponseMessage Delete([FromODataUri] int key)

    // PUT /odata/Products(1)/ODataRouting.Models.Book
    public HttpResponseMessage PutBook([FromODataUri] int key, Book item)

    // PATCH /odata/Products(1)/ODataRouting.Models.Book
    public HttpResponseMessage PatchBook([FromODataUri] int key, Delta<Book> item)

    // DELETE /odata/Products(1)/ODataRouting.Models.Book
    public HttpResponseMessage DeleteBook([FromODataUri] int key)

    //  GET /odata/Products(1)/Supplier
    public Supplier GetSupplierFromProduct([FromODataUri] int key)

    // GET /odata/Products(1)/ODataRouting.Models.Book/Author
    public Author GetAuthorFromBook([FromODataUri] int key)

    // POST /odata/Products(1)/$links/Supplier
    public HttpResponseMessage CreateLink([FromODataUri] int key,
        string navigationProperty, [FromBody] Uri link)

    // DELETE /odata/Products(1)/$links/Supplier
    public HttpResponseMessage DeleteLink([FromODataUri] int key,
        string navigationProperty, [FromBody] Uri link)

    // DELETE /odata/Products(1)/$links/Parts(1)
    public HttpResponseMessage DeleteLink([FromODataUri] int key, string relatedKey, string
navigationProperty)

    // GET odata/Products(1)/Name
    // GET odata/Products(1)/Name/$value
    public HttpResponseMessage GetNameFromProduct([FromODataUri] int key)

    // GET /odata/Products(1)/ODataRouting.Models.Book/Title
    // GET /odata/Products(1)/ODataRouting.Models.Book/Title/$value
    public HttpResponseMessage GetTitleFromBook([FromODataUri] int key)
}
```

Custom Routing Conventions

Currently the built-in conventions do not cover all possible OData URIs. You can add new conventions by implementing the **IODataRoutingConvention** interface. This interface has two methods:

```
string SelectController(ODataPath odataPath, HttpRequestMessage request);
string SelectAction(ODataPath odataPath, HttpControllerContext controllerContext,
    ILookup<string, HttpActionDescriptor> actionMap);
```

- **SelectController** returns the name of the controller.
- **SelectAction** returns the name of the action.

For both methods, if the convention does not apply to that request, the method should return null.

The **ODataPath** parameter represents the parsed OData resource path. It contains a list of **ODataPathSegment** instances, one for each segment of the resource path. **ODataPathSegment** is an abstract class; each segment type is represented by a class that derives from **ODataPathSegment**.

The **ODataPath.TemplatePath** property is a string that represents the concatenation all of the path segments. For example, if the URI is `/Products(1)/Supplier`, the path template is "~/entityset/key/navigation". Notice that the segments don't correspond directly to URI segments. For example, the entity key (1) is represented as its own **ODataPathSegment**.

Typically, an implementation of **IODataRoutingConvention** does the following:

1. Compare the path template to see if this convention applies to the current request. If it does not apply, return null.
2. If the convention applies, use properties of the **ODataPathSegment** instances to derive controller and action names.
3. For actions, add any values to the route dictionary that should bind to the action parameters (typically entity keys).

Let's look at a specific example. The built-in routing conventions do not support indexing into a navigation collection. In other words, there is no convention for URIs like the following:

```
/odata/Products(1)/Suppliers(1)
```

Here is a custom routing convention to handle this type of query.

```
using Microsoft.Data.Edm;
using System.Linq;
using System.Net.Http;
using System.Web.Http.Controllers;
using System.Web.Http.OData.Routing;
using System.Web.Http.OData.Routing.Conventions;

namespace ODataRouting
{
    public class NavigationIndexRoutingConvention : EntitySetRoutingConvention
    {
        public override string SelectAction(ODataPath odataPath, HttpControllerContext context,
            ILookup<string, HttpActionDescriptor> actionMap)
        {
            if (context.Request.Method == HttpMethod.Get &&
                odataPath.PathTemplate == "~/entityset/key/navigation/key")
            {
                NavigationPathSegment navigationSegment = odataPath.Segments[2] as NavigationPathSegment;
                IEdmNavigationProperty navigationProperty = navigationSegment.NavigationProperty.Partner;
                IEdmEntityType declaringType = navigationProperty.DeclaringType as IEdmEntityType;

                string actionName = "Get" + declaringType.Name;
                if (actionMap.Contains(actionName))
                {
                    // Add keys to route data, so they will bind to action parameters.
                    KeyValuePathSegment keyValueSegment = odataPath.Segments[1] as KeyValuePathSegment;
                    context.RouteData.Values[ODataRouteConstants.Key] = keyValueSegment.Value;

                    KeyValuePathSegment relatedKeySegment = odataPath.Segments[3] as KeyValuePathSegment;
                    context.RouteData.Values[ODataRouteConstants.RelatedKey] = relatedKeySegment.Value;

                    return actionName;
                }
            }
            // Not a match.
            return null;
        }
    }
}
```

Notes:

1. I derive from **EntitySetRoutingConvention**, because the **SelectController** method in that class is appropriate for this new routing convention. That means I don't need to re-implement **SelectController**.
2. The convention applies only to GET requests, and only when the path template is "~/entityset/key/navigation/key".
3. The action name is "Get{EntityType}", where *{EntityType}* is the type of the navigation collection. For example, "GetSupplier". You can use any naming convention that you like — just make sure your controller actions match.
4. The action takes two parameters named *key* and *relatedKey*. (For a list of some predefined parameter names, see ODataRouteConstants.)

The next step is adding the new convention to the list of routing conventions. This happens during configuration, as shown in the following code:

```
using ODataRouting.Models;
using System.Web.Http;
using System.Web.Http.OData.Builder;
using System.Web.Http.OData.Routing;
using System.Web.Http.OData.Routing.Conventions;

namespace ODataRouting
{
    public static class WebApiConfig
    {
        public static void Register(HttpConfiguration config)
        {
            ODataModelBuilder modelBuilder = new ODataConventionModelBuilder();
            // Create EDM (not shown).

            // Create the default collection of built-in conventions.
            var conventions = ODataRoutingConventions.CreateDefault();
            // Insert the custom convention at the start of the collection.
            conventions.Insert(0, new NavigationIndexRoutingConvention());

            config.Routes.MapODataRoute(routeName: "ODataRoute",
                routePrefix: "odata",
                model: modelBuilder.GetEdmModel(),
                pathHandler: new DefaultODataPathHandler(),
                routingConventions: conventions);

        }
    }
}
```

Here are some other sample routing conventions that be useful to study:

- CompositeKeyRoutingConvention
- CustomNavigationRoutingConvention
- NonBindableActionRoutingConvention
- ODataVersionRouteConstraint

And of course Web API itself is open-source, so you can see the source code for the built-in routing conventions. These are defined in the **System.Web.Http.OData.Routing.Conventions** namespace.

Security Guidance for ASP.NET Web API 2 OData

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

This topic describes some of the security issues that you should consider when exposing a dataset through OData for ASP.NET Web API 2 on ASP.NET 4.x.

EDM Security

The query semantics are based on the entity data model (EDM), not the underlying model types. You can exclude a property from the EDM and it will not be visible to the query. For example, suppose your model includes an Employee type with a Salary property. You might want to exclude this property from the EDM to hide it from clients.

There are two ways to exclude a property from the EDM. You can set the **[IgnoreDataMember]** attribute on the property in the model class:

```
public class Employee
{
    public string Name { get; set; }
    public string Title { get; set; }
    [IgnoreDataMember]
    public decimal Salary { get; set; } // Not visible in the EDM
}
```

You can also remove the property from the EDM programmatically:

```
var employees = modelBuilder.EntitySet<Employee>("Employees");
employees.EntityType.Ignore(emp => emp.Salary);
```

Query Security

A malicious or naive client may be able to construct a query that takes a very long time to execute. In the worst case this can disrupt access to your service.

The **[Queryable]** attribute is an action filter that parses, validates, and applies the query. The filter converts the query options into a LINQ expression. When the OData controller returns an **IQueryable** type, the **IQueryable** LINQ provider converts the LINQ expression into a query. Therefore, performance depends on the LINQ provider that is used, and also on the particular characteristics of your dataset or database schema.

For more information about using OData query options in ASP.NET Web API, see Supporting OData Query Options.

If you know that all clients are trusted (for example, in an enterprise environment), or if your dataset is small, query performance might not be an issue. Otherwise, you should consider the following recommendations.

- Test your service with various queries and profile the DB.
- Enable server-driven paging, to avoid returning a large data set in one query. For more information, see Server-Driven Paging.

```
// Enable server-driven paging.
[Queryable(PageSize=10)]
```

- Do you need $filter and $orderby? Some applications might allow client paging, using $top and $skip, but disable the other query options.

```
// Allow client paging but no other query options.
[Queryable(AllowedQueryOptions=AllowedQueryOptions.Skip |
                               AllowedQueryOptions.Top)]
```

- Consider restricting $orderby to properties in a clustered index. Sorting large data without a clustered index is slow.

```
// Set the allowed $orderby properties.
[Queryable(AllowedOrderByProperties="Id,Name")] // Comma separated list
```

- Maximum node count: The **MaxNodeCount** property on **[Queryable]** sets the maximum number nodes allowed in the $filter syntax tree. The default value is 100, but you may want to set a lower value, because a large number of nodes can be slow to compile. This is particularly true if you are using LINQ to Objects (i.e., LINQ queries on a collection in memory, without the use of an intermediate LINQ provider).

```
// Set the maximum node count.
[Queryable(MaxNodeCount=20)]
```

- Consider disabling the any() and all() functions, as these can be slow.

```
// Disable any() and all() functions.
[Queryable(AllowedFunctions= AllowedFunctions.AllFunctions &
    ~AllowedFunctions.All & ~AllowedFunctions.Any)]
```

- If any string properties contain large strings—for example, a product description or a blog entry—consider disabling the string functions.

```
// Disable string functions.
[Queryable(AllowedFunctions=AllowedFunctions.AllFunctions &
    ~AllowedFunctions.AllStringFunctions)]
```

- Consider disallowing filtering on navigation properties. Filtering on navigation properties can result in a join, which might be slow, depending on your database schema. The following code shows a query validator that prevents filtering on navigation properties. For more information about query validators, see Query Validation.

```
// Validator to prevent filtering on navigation properties.
public class MyFilterQueryValidator : FilterQueryValidator
{
    public override void ValidateNavigationPropertyNode(
        Microsoft.Data.OData.Query.SemanticAst.QueryNode sourceNode,
        Microsoft.Data.Edm.IEdmNavigationProperty navigationProperty,
        ODataValidationSettings settings)
    {
        throw new ODataException("No navigation properties");
    }
}
```

- Consider restricting $filter queries by writing a validator that is customized for your database. For example, consider these two queries:
  - All movies with actors whose last name starts with 'A'.
  - All movies released in 1994.

    Unless movies are indexed by actors, the first query might require the DB engine to scan the entire list of movies. Whereas the second query might be acceptable, assuming movies are indexed by release year.

    The following code shows a validator that allows filtering on the "ReleaseYear" and "Title" properties but no other properties.

```
// Validator to restrict which properties can be used in $filter expressions.
public class MyFilterQueryValidator : FilterQueryValidator
{
    static readonly string[] allowedProperties = { "ReleaseYear", "Title" };

    public override void ValidateSingleValuePropertyAccessNode(
        SingleValuePropertyAccessNode propertyAccessNode,
        ODataValidationSettings settings)
    {
        string propertyName = null;
        if (propertyAccessNode != null)
        {
            propertyName = propertyAccessNode.Property.Name;
        }

        if (propertyName != null && !allowedProperties.Contains(propertyName))
        {
            throw new ODataException(
                String.Format("Filter on {0} not allowed", propertyName));
        }
        base.ValidateSingleValuePropertyAccessNode(propertyAccessNode, settings);
    }
}
```

- In general, consider which $filter functions you need. If your clients do not need the full expressiveness of $filter, you can limit the allowed functions.

Serialization and Model Binding in ASP.NET Web API

2/20/2020 • 2 minutes to read • Edit Online

How ASP.NET Web API binds HTTP messages to domain models, and how to work with media formats in Web API.

- Media Formatters in Web API 2
- JSON and XML Serialization in Web API
- BSON Support in Web API 2.1
- Content Negotiation in Web API
- Model Validation in Web API
- Parameter Binding in Web API

Media Formatters in ASP.NET Web API 2

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

This tutorial shows how to support additional media formats in ASP.NET Web API.

Internet Media Types

A media type, also called a MIME type, identifies the format of a piece of data. In HTTP, media types describe the format of the message body. A media type consists of two strings, a type and a subtype. For example:

- text/html
- image/png
- application/json

When an HTTP message contains an entity-body, the Content-Type header specifies the format of the message body. This tells the receiver how to parse the contents of the message body.

For example, if an HTTP response contains a PNG image, the response might have the following headers.

```
HTTP/1.1 200 OK
Content-Length: 95267
Content-Type: image/png
```

When the client sends a request message, it can include an Accept header. The Accept header tells the server which media type(s) the client wants from the server. For example:

```
Accept: text/html,application/xhtml+xml,application/xml
```

This header tells the server that the client wants either HTML, XHTML, or XML.

The media type determines how Web API serializes and deserializes the HTTP message body. Web API has built-in support for XML, JSON, BSON, and form-urlencoded data, and you can support additional media types by writing a *media formatter*.

To create a media formatter, derive from one of these classes:

- MediaTypeFormatter. This class uses asynchronous read and write methods.
- BufferedMediaTypeFormatter. This class derives from **MediaTypeFormatter** but uses synchronous read/write methods.

Deriving from **BufferedMediaTypeFormatter** is simpler, because there is no asynchronous code, but it also means the calling thread can block during I/O.

Example: Creating a CSV Media Formatter

The following example shows a media type formatter that can serialize a Product object to a comma-separated values (CSV) format. This example uses the Product type defined in the tutorial Creating a Web API that Supports CRUD Operations. Here is the definition of the Product object:

```
namespace ProductStore.Models
{
    public class Product
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public string Category { get; set; }
        public decimal Price { get; set; }
    }
}
```

To implement a CSV formatter, define a class that derives from **BufferedMediaTypeFormatter**:

```
using System;
using System.Collections.Generic;
using System.IO;
using System.Net.Http;
using System.Net.Http.Formatting;
using System.Net.Http.Headers;
using ProductStore.Models;

namespace ProductStore.Formatters
{
    public class ProductCsvFormatter : BufferedMediaTypeFormatter
    {
    }
}
```

In the constructor, add the media types that the formatter supports. In this example, the formatter supports a single media type, "text/csv":

```
public ProductCsvFormatter()
{
    // Add the supported media type.
    SupportedMediaTypes.Add(new MediaTypeHeaderValue("text/csv"));
}
```

Override the **CanWriteType** method to indicate which types the formatter can serialize:

```
public override bool CanWriteType(System.Type type)
{
    if (type == typeof(Product))
    {
        return true;
    }
    else
    {
        Type enumerableType = typeof(IEnumerable<Product>);
        return enumerableType.IsAssignableFrom(type);
    }
}
```

In this example, the formatter can serialize single `Product` objects as well as collections of `Product` objects.

Similarly, override the **CanReadType** method to indicate which types the formatter can deserialize. In this example, the formatter does not support deserialization, so the method simply returns **false**.

```
public override bool CanReadType(Type type)
{
    return false;
}
```

Finally, override the **WriteToStream** method. This method serializes a type by writing it to a stream. If your formatter supports deserialization, also override the **ReadFromStream** method.

```
public override void WriteToStream(Type type, object value, Stream writeStream, HttpContent content)
{
    using (var writer = new StreamWriter(writeStream))
    {
        var products = value as IEnumerable<Product>;
        if (products != null)
        {
            foreach (var product in products)
            {
                WriteItem(product, writer);
            }
        }
        else
        {
            var singleProduct = value as Product;
            if (singleProduct == null)
            {
                throw new InvalidOperationException("Cannot serialize type");
            }
            WriteItem(singleProduct, writer);
        }
    }
}

// Helper methods for serializing Products to CSV format.
private void WriteItem(Product product, StreamWriter writer)
{
    writer.WriteLine("{0},{1},{2},{3}", Escape(product.Id),
        Escape(product.Name), Escape(product.Category), Escape(product.Price));
}

static char[] _specialChars = new char[] { ',', '\n', '\r', '"' };

private string Escape(object o)
{
    if (o == null)
    {
        return "";
    }
    string field = o.ToString();
    if (field.IndexOfAny(_specialChars) != -1)
    {
        // Delimit the entire field with quotes and replace embedded quotes with "".
        return String.Format("\"{0}\"", field.Replace("\"", "\"\""));
    }
    else return field;
}
```

Adding a Media Formatter to the Web API Pipeline

To add a media type formatter to the Web API pipeline, use the **Formatters** property on the **HttpConfiguration** object.

```
public static void ConfigureApis(HttpConfiguration config)
{
    config.Formatters.Add(new ProductCsvFormatter());
}
```

Character Encodings

Optionally, a media formatter can support multiple character encodings, such as UTF-8 or ISO 8859-1.

In the constructor, add one or more System.Text.Encoding types to the **SupportedEncodings** collection. Put the default encoding first.

```
public ProductCsvFormatter()
{
    SupportedMediaTypes.Add(new MediaTypeHeaderValue("text/csv"));

    // New code:
    SupportedEncodings.Add(new UTF8Encoding(encoderShouldEmitUTF8Identifier: false));
    SupportedEncodings.Add(Encoding.GetEncoding("iso-8859-1"));
}
```

In the **WriteToStream** and **ReadFromStream** methods, call MediaTypeFormatter.SelectCharacterEncoding to select the preferred character encoding. This method matches the request headers against the list of supported encodings. Use the returned **Encoding** when you read or write from the stream:

```
public override void WriteToStream(Type type, object value, Stream writeStream, HttpContent content)
{
    Encoding effectiveEncoding = SelectCharacterEncoding(content.Headers);

    using (var writer = new StreamWriter(writeStream, effectiveEncoding))
    {
        // Write the object (code not shown)
    }
}
```

JSON and XML Serialization in ASP.NET Web API

4/6/2020 • 9 minutes to read • Edit Online

by Mike Wasson

This article describes the JSON and XML formatters in ASP.NET Web API.

In ASP.NET Web API, a *media-type formatter* is an object that can:

- Read CLR objects from an HTTP message body
- Write CLR objects into an HTTP message body

Web API provides media-type formatters for both JSON and XML. The framework inserts these formatters into the pipeline by default. Clients can request either JSON or XML in the Accept header of the HTTP request.

Contents

  - Read-Only Properties
  - Dates
  - Indenting
  - Camel Casing
  - Anonymous and Weakly-Typed Objects
- XML Media-Type Formatter
  - Read-Only Properties
  - Dates
  - Indenting
  - Setting Per-Type XML Serializers
- Removing the JSON or XML Formatter
- Handling Circular Object References
- Testing Object Serialization

JSON Media-Type Formatter

JSON formatting is provided by the **JsonMediaTypeFormatter** class. By default, **JsonMediaTypeFormatter** uses the Json.NET library to perform serialization. Json.NET is a third-party open source project.

If you prefer, you can configure the **JsonMediaTypeFormatter** class to use the **DataContractJsonSerializer** instead of Json.NET. To do so, set the **UseDataContractJsonSerializer** property to **true**:

```
var json = GlobalConfiguration.Configuration.Formatters.JsonFormatter;
json.UseDataContractJsonSerializer = true;
```

JSON Serialization

This section describes some specific behaviors of the JSON formatter, using the default Json.NET serializer. This is not meant to be comprehensive documentation of the Json.NET library; for more information, see the Json.NET Documentation.

What Gets Serialized?

By default, all public properties and fields are included in the serialized JSON. To omit a property or field, decorate it with the **JsonIgnore** attribute.

```
public class Product
{
    public string Name { get; set; }
    public decimal Price { get; set; }
    [JsonIgnore]
    public int ProductCode { get; set; } // omitted
}
```

If you prefer an "opt-in" approach, decorate the class with the **DataContract** attribute. If this attribute is present, members are ignored unless they have the **DataMember**. You can also use **DataMember** to serialize private members.

```
[DataContract]
public class Product
{
    [DataMember]
    public string Name { get; set; }
    [DataMember]
    public decimal Price { get; set; }
    public int ProductCode { get; set; }  // omitted by default
}
```

Read-Only Properties

Read-only properties are serialized by default.

Dates

By default, Json.NET writes dates in ISO 8601 format. Dates in UTC (Coordinated Universal Time) are written with a "Z" suffix. Dates in local time include a time-zone offset. For example:

```
2012-07-27T18:51:45.53403Z         // UTC
2012-07-27T11:51:45.53403-07:00    // Local
```

By default, Json.NET preserves the time zone. You can override this by setting the DateTimeZoneHandling property:

```
// Convert all dates to UTC
var json = GlobalConfiguration.Configuration.Formatters.JsonFormatter;
json.SerializerSettings.DateTimeZoneHandling = Newtonsoft.Json.DateTimeZoneHandling.Utc;
```

If you prefer to use Microsoft JSON date format (`"\/Date(ticks)\/"`) instead of ISO 8601, set the **DateFormatHandling** property on the serializer settings:

```
var json = GlobalConfiguration.Configuration.Formatters.JsonFormatter;
json.SerializerSettings.DateFormatHandling
= Newtonsoft.Json.DateFormatHandling.MicrosoftDateFormat;
```

Indenting

To write indented JSON, set the **Formatting** setting to **Formatting.Indented**:

```
var json = GlobalConfiguration.Configuration.Formatters.JsonFormatter;
json.SerializerSettings.Formatting = Newtonsoft.Json.Formatting.Indented;
```

Camel Casing

To write JSON property names with camel casing, without changing your data model, set the **CamelCasePropertyNamesContractResolver** on the serializer:

```
var json = GlobalConfiguration.Configuration.Formatters.JsonFormatter;
json.SerializerSettings.ContractResolver = new CamelCasePropertyNamesContractResolver();
```

Anonymous and Weakly-Typed Objects

An action method can return an anonymous object and serialize it to JSON. For example:

```
public object Get()
{
    return new {
        Name = "Alice",
        Age = 23,
        Pets = new List<string> { "Fido", "Polly", "Spot" }
    };
}
```

The response message body will contain the following JSON:

```
{"Name":"Alice","Age":23,"Pets":["Fido","Polly","Spot"]}
```

If your web API receives loosely structured JSON objects from clients, you can deserialize the request body to a **Newtonsoft.Json.Linq.JObject** type.

```
public void Post(JObject person)
{
    string name = person["Name"].ToString();
    int age = person["Age"].ToObject<int>();
}
```

However, it is usually better to use strongly typed data objects. Then you don't need to parse the data yourself, and you get the benefits of model validation.

The XML serializer does not support anonymous types or **JObject** instances. If you use these features for your JSON data, you should remove the XML formatter from the pipeline, as described later in this article.

XML Media-Type Formatter

XML formatting is provided by the **XmlMediaTypeFormatter** class. By default, **XmlMediaTypeFormatter** uses the **DataContractSerializer** class to perform serialization.

If you prefer, you can configure the **XmlMediaTypeFormatter** to use the **XmlSerializer** instead of the **DataContractSerializer**. To do so, set the **UseXmlSerializer** property to **true**:

```
var xml = GlobalConfiguration.Configuration.Formatters.XmlFormatter;
xml.UseXmlSerializer = true;
```

The **XmlSerializer** class supports a narrower set of types than **DataContractSerializer**, but gives more control

over the resulting XML. Consider using **XmlSerializer** if you need to match an existing XML schema.

XML Serialization

This section describes some specific behaviors of the XML formatter, using the default **DataContractSerializer**.

By default, the DataContractSerializer behaves as follows:

- All public read/write properties and fields are serialized. To omit a property or field, decorate it with the **IgnoreDataMember** attribute.
- Private and protected members are not serialized.
- Read-only properties are not serialized. (However, the contents of a read-only collection property are serialized.)
- Class and member names are written in the XML exactly as they appear in the class declaration.
- A default XML namespace is used.

If you need more control over the serialization, you can decorate the class with the **DataContract** attribute. When this attribute is present, the class is serialized as follows:

- "Opt in" approach: Properties and fields are not serialized by default. To serialize a property or field, decorate it with the **DataMember** attribute.
- To serialize a private or protected member, decorate it with the **DataMember** attribute.
- Read-only properties are not serialized.
- To change how the class name appears in the XML, set the *Name* parameter in the **DataContract** attribute.
- To change how a member name appears in the XML, set the *Name* parameter in the **DataMember** attribute.
- To change the XML namespace, set the *Namespace* parameter in the **DataContract** class.

Read-Only Properties

Read-only properties are not serialized. If a read-only property has a backing private field, you can mark the private field with the **DataMember** attribute. This approach requires the **DataContract** attribute on the class.

```
[DataContract]
public class Product
{
    [DataMember]
    private int pcode;  // serialized

    // Not serialized (read-only)
    public int ProductCode { get { return pcode; } }
}
```

Dates

Dates are written in ISO 8601 format. For example, "2012-05-23T20:21:37.9116538Z".

Indenting

To write indented XML, set the **Indent** property to **true**:

```
var xml = GlobalConfiguration.Configuration.Formatters.XmlFormatter;
xml.Indent = true;
```

Setting Per-Type XML Serializers

You can set different XML serializers for different CLR types. For example, you might have a particular data object that requires **XmlSerializer** for backward compatibility. You can use **XmlSerializer** for this object and continue to use **DataContractSerializer** for other types.

To set an XML serializer for a particular type, call **SetSerializer**.

```
var xml = GlobalConfiguration.Configuration.Formatters.XmlFormatter;
// Use XmlSerializer for instances of type "Product":
xml.SetSerializer<Product>(new XmlSerializer(typeof(Product)));
```

You can specify an **XmlSerializer** or any object that derives from **XmlObjectSerializer**.

Removing the JSON or XML Formatter

You can remove the JSON formatter or the XML formatter from the list of formatters, if you do not want to use them. The main reasons to do this are:

- To restrict your web API responses to a particular media type. For example, you might decide to support only JSON responses, and remove the XML formatter.
- To replace the default formatter with a custom formatter. For example, you could replace the JSON formatter with your own custom implementation of a JSON formatter.

The following code shows how to remove the default formatters. Call this from your **Application_Start** method, defined in Global.asax.

```
void ConfigureApi(HttpConfiguration config)
{
    // Remove the JSON formatter
    config.Formatters.Remove(config.Formatters.JsonFormatter);

    // or

    // Remove the XML formatter
    config.Formatters.Remove(config.Formatters.XmlFormatter);
}
```

Handling Circular Object References

By default, the JSON and XML formatters write all objects as values. If two properties refer to the same object, or if the same object appears twice in a collection, the formatter will serialize the object twice. This is a particular problem if your object graph contains cycles, because the serializer will throw an exception when it detects a loop in the graph.

Consider the following object models and controller.

```
public class Employee
{
    public string Name { get; set; }
    public Department Department { get; set; }
}

public class Department
{
    public string Name { get; set; }
    public Employee Manager { get; set; }
}

public class DepartmentsController : ApiController
{
    public Department Get(int id)
    {
        Department sales = new Department() { Name = "Sales" };
        Employee alice = new Employee() { Name = "Alice", Department = sales };
        sales.Manager = alice;
        return sales;
    }
}
```

Invoking this action will cause the formatter to throw an exception, which translates to a status code 500 (Internal Server Error) response to the client.

To preserve object references in JSON, add the following code to **Application_Start** method in the Global.asax file:

```
var json = GlobalConfiguration.Configuration.Formatters.JsonFormatter;
json.SerializerSettings.PreserveReferencesHandling =
    Newtonsoft.Json.PreserveReferencesHandling.All;
```

Now the controller action will return JSON that looks like this:

```
{"$id":"1","Name":"Sales","Manager":{"$id":"2","Name":"Alice","Department":{"$ref":"1"}}}
```

Notice that the serializer adds an "$id" property to both objects. Also, it detects that the Employee.Department property creates a loop, so it replaces the value with an object reference: {"$ref":"1"}.

> **NOTE**
> Object references are not standard in JSON. Before using this feature, consider whether your clients will be able to parse the results. It might be better simply to remove cycles from the graph. For example, the link from Employee back to Department is not really needed in this example.

To preserve object references in XML, you have two options. The simpler option is to add `[DataContract(IsReference=true)]` to your model class. The *IsReference* parameter enables object references. Remember that **DataContract** makes serialization opt-in, so you will also need to add **DataMember** attributes to the properties:

```
[DataContract(IsReference=true)]
public class Department
{
    [DataMember]
    public string Name { get; set; }
    [DataMember]
    public Employee Manager { get; set; }
}
```

Now the formatter will produce XML similar to following:

```
<Department xmlns:i="http://www.w3.org/2001/XMLSchema-instance" z:Id="i1"
            xmlns:z="http://schemas.microsoft.com/2003/10/Serialization/"
            xmlns="http://schemas.datacontract.org/2004/07/Models">
  <Manager>
    <Department z:Ref="i1" />
    <Name>Alice</Name>
  </Manager>
  <Name>Sales</Name>
</Department>
```

If you want to avoid attributes on your model class, there is another option: Create a new type-specific **DataContractSerializer** instance and set *preserveObjectReferences* to **true** in the constructor. Then set this instance as a per-type serializer on the XML media-type formatter. The following code show how to do this:

```
var xml = GlobalConfiguration.Configuration.Formatters.XmlFormatter;
var dcs = new DataContractSerializer(typeof(Department), null, int.MaxValue,
    false, /* preserveObjectReferences: */ true, null);
xml.SetSerializer<Department>(dcs);
```

Testing Object Serialization

As you design your web API, it is useful to test how your data objects will be serialized. You can do this without creating a controller or invoking a controller action.

```
string Serialize<T>(MediaTypeFormatter formatter, T value)
{
    // Create a dummy HTTP Content.
    Stream stream = new MemoryStream();
    var content = new StreamContent(stream);
    /// Serialize the object.
    formatter.WriteToStreamAsync(typeof(T), value, stream, content, null).Wait();
    // Read the serialized string.
    stream.Position = 0;
    return content.ReadAsStringAsync().Result;
}

T Deserialize<T>(MediaTypeFormatter formatter, string str) where T : class
{
    // Write the serialized string to a memory stream.
    Stream stream = new MemoryStream();
    StreamWriter writer = new StreamWriter(stream);
    writer.Write(str);
    writer.Flush();
    stream.Position = 0;
    // Deserialize to an object of type T
    return formatter.ReadFromStreamAsync(typeof(T), stream, null, null).Result as T;
}

// Example of use
void TestSerialization()
{
    var value = new Person() { Name = "Alice", Age = 23 };

    var xml = new XmlMediaTypeFormatter();
    string str = Serialize(xml, value);

    var json = new JsonMediaTypeFormatter();
    str = Serialize(json, value);

    // Round trip
    Person person2 = Deserialize<Person>(json, str);
}
```

BSON Support in ASP.NET Web API 2.1

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

This topic shows how to use BSON in your Web API controller (server side) and in a .NET client app. Web API 2.1 introduces support for BSON.

What is BSON?

BSON is a binary serialization format. "BSON" stands for "Binary JSON", but BSON and JSON are serialized very differently. BSON is "JSON-like", because objects are represented as name-value pairs, similar to JSON. Unlike JSON, numeric data types are stored as bytes, not strings

BSON was designed to be lightweight, easy to scan, and fast to encode/decode.

- BSON is comparable in size to JSON. Depending on the data, a BSON payload may be smaller or larger than a JSON payload. For serializing binary data, such as an image file, BSON is smaller than JSON, because the binary data is not base64-encoded.
- BSON documents are easy to scan because elements are prefixed with a length field, so a parser can skip elements without decoding them.
- Encoding and decoding are efficient, because numeric data types are stored as numbers, not strings.

Native clients, such as .NET client apps, can benefit from using BSON in place of text-based formats such as JSON or XML. For browser clients, you will probably want to stick with JSON, because JavaScript can directly convert the JSON payload.

Fortunately, Web API uses content negotiation, so your API can support both formats and let the client choose.

Enabling BSON on the Server

In your Web API configuration, add the **BsonMediaTypeFormatter** to the formatters collection.

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.Formatters.Add(new BsonMediaTypeFormatter());

        // Other Web API configuration not shown...
    }
}
```

Now if the client requests "application/bson", Web API will use the BSON formatter.

To associate BSON with other media types, add them to the SupportedMediaTypes collection. The following code adds "application/vnd.contoso" to the supported media types:

```
var bson = new BsonMediaTypeFormatter();
bson.SupportedMediaTypes.Add(new MediaTypeHeaderValue("application/vnd.contoso"));
config.Formatters.Add(bson);
```

Example HTTP Session

For this example, we'll use the following model class plus a simple Web API controller:

```
public class Book
{
    public int Id { get; set; }
    public string Title { get; set; }
    public string Author { get; set; }
    public decimal Price { get; set; }
    public DateTime PublicationDate { get; set; }
}

public class BooksController : ApiController
{
    public IHttpActionResult GetBook(int id)
    {
        var book = new Book()
        {
            Id = id,
            Author = "Charles Dickens",
            Title = "Great Expectations",
            Price = 9.95M,
            PublicationDate = new DateTime(2014, 1, 20)
        };

        return Ok(book);
    }
}
```

A client might send the following HTTP request:

```
GET http://localhost:15192/api/books/1 HTTP/1.1
User-Agent: Fiddler
Host: localhost:15192
Accept: application/bson
```

Here is the response:

```
HTTP/1.1 200 OK
Content-Type: application/bson; charset=utf-8
Date: Fri, 17 Jan 2014 01:05:40 GMT
Content-Length: 111

.....Id......Title.....Great Expectations..Author.....Charles Dickens..Price..........PublicationDate.........
```

Here I've replaced the binary data with "." characters. The following screen shot from Fiddler shows the raw hex values.

```
48 54 54 50 2F 31 2E 31 20 32 30 30 20 4F 4B 0D 0A 43 61 63 68   HTTP/1.1 200 OK..Cach

```

Using BSON with HttpClient

.NET clients apps can use the BSON formatter with **HttpClient**. For more information about **HttpClient**, see Calling a Web API From a .NET Client.

The following code sends a GET request that accepts BSON, and then deserializes the BSON payload in the response.

```
static async Task RunAsync()
{
    using (HttpClient client = new HttpClient())
    {
        client.BaseAddress = new Uri("http://localhost");

        // Set the Accept header for BSON.
        client.DefaultRequestHeaders.Accept.Clear();
        client.DefaultRequestHeaders.Accept.Add(new MediaTypeWithQualityHeaderValue("application/bson"));

        // Send GET request.
        result = await client.GetAsync("api/books/1");
        result.EnsureSuccessStatusCode();

        // Use BSON formatter to deserialize the result.
        MediaTypeFormatter[] formatters = new MediaTypeFormatter[] {
            new BsonMediaTypeFormatter()
        };

        var book = await result.Content.ReadAsAsync<Book>(formatters);
    }
}
```

To request BSON from the server, set the Accept header to "application/bson":

```
client.DefaultRequestHeaders.Accept.Clear();
client.DefaultRequestHeaders.Accept.Add(new
    MediaTypeWithQualityHeaderValue("application/bson"));
```

To deserialize the response body, use the **BsonMediaTypeFormatter**. This formatter is not in the default formatters collection, so you have to specify it when you read the response body:

```
MediaTypeFormatter[] formatters = new MediaTypeFormatter[] {
    new BsonMediaTypeFormatter()
};

var book = await result.Content.ReadAsAsync<Book>(formatters);
```

The next example shows how to send a POST request that contains BSON.

```
static async Task RunAsync()
{
    using (HttpClient client = new HttpClient())
    {
        client.BaseAddress = new Uri("http://localhost:15192");

        // Set the Accept header for BSON.
        client.DefaultRequestHeaders.Accept.Clear();
        client.DefaultRequestHeaders.Accept.Add(new MediaTypeWithQualityHeaderValue("application/bson"));

        var book = new Book()
        {
            Author = "Jane Austen",
            Title = "Emma",
            Price = 9.95M,
            PublicationDate = new DateTime(1815, 1, 1)
        };

        // POST using the BSON formatter.
        MediaTypeFormatter bsonFormatter = new BsonMediaTypeFormatter();
        var result = await client.PostAsync("api/books", book, bsonFormatter);
        result.EnsureSuccessStatusCode();
    }
}
```

Much of this code is the same as the previous example. But in the **PostAsync** method, specify **BsonMediaTypeFormatter** as the formatter:

```
MediaTypeFormatter bsonFormatter = new BsonMediaTypeFormatter();
var result = await client.PostAsync("api/books", book, bsonFormatter);
```

Serializing Top-Level Primitive Types

Every BSON document is a list of key/value pairs.The BSON specification does not define a syntax for serializing a single raw value, such as an integer or string.

To work around this limitation, the **BsonMediaTypeFormatter** treats primitive types as a special case. Before serializing, it converts the value into a key/value pair with the key "Value". For example, suppose your API controller returns an integer:

```
public class ValuesController : ApiController
{
    public IHttpActionResult Get()
    {
        return Ok(42);
    }
}
```

Before serializing, the BSON formatter converts this to the following key/value pair:

```
{ "Value": 42 }
```

When you deserialize, the formatter converts the data back to the original value. However, clients using a different BSON parser will need to handle this case, if your web API returns raw values. In general, you should consider returning structured data, rather than raw values.

Web API BSON Sample

Media Formatters

Content Negotiation in ASP.NET Web API

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

This article describes how ASP.NET Web API implements content negotiation for ASP.NET 4.x.

The HTTP specification (RFC 2616) defines content negotiation as "the process of selecting the best representation for a given response when there are multiple representations available." The primary mechanism for content negotiation in HTTP are these request headers:

- **Accept:** Which media types are acceptable for the response, such as "application/json," "application/xml," or a custom media type such as "application/vnd.example+xml"
- **Accept-Charset:** Which character sets are acceptable, such as UTF-8 or ISO 8859-1.
- **Accept-Encoding:** Which content encodings are acceptable, such as gzip.
- **Accept-Language:** The preferred natural language, such as "en-us".

The server can also look at other portions of the HTTP request. For example, if the request contains an X-Requested-With header, indicating an AJAX request, the server might default to JSON if there is no Accept header.

In this article, we'll look at how Web API uses the Accept and Accept-Charset headers. (At this time, there is no built-in support for Accept-Encoding or Accept-Language.)

Serialization

If a Web API controller returns a resource as CLR type, the pipeline serializes the return value and writes it into the HTTP response body.

For example, consider the following controller action:

```
public Product GetProduct(int id)
{
    var item = _products.FirstOrDefault(p => p.ID == id);
    if (item == null)
    {
        throw new HttpResponseException(HttpStatusCode.NotFound);
    }
    return item;
}
```

A client might send this HTTP request:

```
GET http://localhost.:21069/api/products/1 HTTP/1.1
Host: localhost.:21069
Accept: application/json, text/javascript, */*; q=0.01
```

In response, the server might send:

```
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Content-Length: 57
Connection: Close

{"Id":1,"Name":"Gizmo","Category":"Widgets","Price":1.99}
```

In this example, the client requested either JSON, Javascript, or "anything" (*/*). The server responded with a JSON representation of the `Product` object. Notice that the Content-Type header in the response is set to "application/json".

A controller can also return an **HttpResponseMessage** object. To specify a CLR object for the response body, call the **CreateResponse** extension method:

```
public HttpResponseMessage GetProduct(int id)
{
    var item = _products.FirstOrDefault(p => p.ID == id);
    if (item == null)
    {
        throw new HttpResponseException(HttpStatusCode.NotFound);
    }
    return Request.CreateResponse(HttpStatusCode.OK, item);
}
```

This option gives you more control over the details of the response. You can set the status code, add HTTP headers, and so forth.

The object that serializes the resource is called a *media formatter*. Media formatters derive from the **MediaTypeFormatter** class. Web API provides media formatters for XML and JSON, and you can create custom formatters to support other media types. For information about writing a custom formatter, see Media Formatters.

How Content Negotiation Works

First, the pipeline gets the **IContentNegotiator** service from the **HttpConfiguration** object. It also gets the list of media formatters from the **HttpConfiguration.Formatters** collection.

Next, the pipeline calls **IContentNegotiator.Negotiate**, passing in:

- The type of object to serialize
- The collection of media formatters
- The HTTP request

The **Negotiate** method returns two pieces of information:

- Which formatter to use
- The media type for the response

If no formatter is found, the **Negotiate** method returns **null**, and the client receives HTTP error 406 (Not Acceptable).

The following code shows how a controller can directly invoke content negotiation:

```
public HttpResponseMessage GetProduct(int id)
{
    var product = new Product()
        { Id = id, Name = "Gizmo", Category = "Widgets", Price = 1.99M };

    IContentNegotiator negotiator = this.Configuration.Services.GetContentNegotiator();

    ContentNegotiationResult result = negotiator.Negotiate(
        typeof(Product), this.Request, this.Configuration.Formatters);
    if (result == null)
    {
        var response = new HttpResponseMessage(HttpStatusCode.NotAcceptable);
        throw new HttpResponseException(response));
    }

    return new HttpResponseMessage()
    {
        Content = new ObjectContent<Product>(
            product,          // What we are serializing
            result.Formatter,           // The media formatter
            result.MediaType.MediaType  // The MIME type
        )
    };
}
```

This code is equivalent to the what the pipeline does automatically.

Default Content Negotiator

The **DefaultContentNegotiator** class provides the default implementation of **IContentNegotiator**. It uses several criteria to select a formatter.

First, the formatter must be able to serialize the type. This is verified by calling **MediaTypeFormatter.CanWriteType**.

Next, the content negotiator looks at each formatter and evaluates how well it matches the HTTP request. To evaluate the match, the content negotiator looks at two things on the formatter:

- The **SupportedMediaTypes** collection, which contains a list of supported media types. The content negotiator tries to match this list against the request Accept header. Note that the Accept header can include ranges. For example, "text/plain" is a match for text/* or */*.
- The **MediaTypeMappings** collection, which contains a list of **MediaTypeMapping** objects. The **MediaTypeMapping** class provides a generic way to match HTTP requests with media types. For example, it could map a custom HTTP header to a particular media type.

If there are multiple matches, the match with the highest quality factor wins. For example:

```
Accept: application/json, application/xml; q=0.9, */*; q=0.1
```

In this example, application/json has an implied quality factor of 1.0, so it is preferred over application/xml.

If no matches are found, the content negotiator tries to match on the media type of the request body, if any. For example, if the request contains JSON data, the content negotiator looks for a JSON formatter.

If there are still no matches, the content negotiator simply picks the first formatter that can serialize the type.

Selecting a Character Encoding

After a formatter is selected, the content negotiator chooses the best character encoding by looking at the

SupportedEncodings property on the formatter, and matching it against the Accept-Charset header in the request (if any).

Model Validation in ASP.NET Web API

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

This article shows how to annotate your models, use the annotations for data validation, and handle validation errors in your web API. When a client sends data to your web API, often you want to validate the data before doing any processing.

Data Annotations

In ASP.NET Web API, you can use attributes from the System.ComponentModel.DataAnnotations namespace to set validation rules for properties on your model. Consider the following model:

```
using System.ComponentModel.DataAnnotations;

namespace MyApi.Models
{
    public class Product
    {
        public int Id { get; set; }
        [Required]
        public string Name { get; set; }
        public decimal Price { get; set; }
        [Range(0, 999)]
        public double Weight { get; set; }
    }
}
```

If you have used model validation in ASP.NET MVC, this should look familiar. The **Required** attribute says that the `Name` property must not be null. The **Range** attribute says that `Weight` must be between zero and 999.

Suppose that a client sends a POST request with the following JSON representation:

```
{ "Id":4, "Price":2.99, "Weight":5 }
```

You can see that the client did not include the `Name` property, which is marked as required. When Web API converts the JSON into a `Product` instance, it validates the `Product` against the validation attributes. In your controller action, you can check whether the model is valid:

```
using MyApi.Models;
using System.Net;
using System.Net.Http;
using System.Web.Http;

namespace MyApi.Controllers
{
    public class ProductsController : ApiController
    {
        public HttpResponseMessage Post(Product product)
        {
            if (ModelState.IsValid)
            {
                // Do something with the product (not shown).

                return new HttpResponseMessage(HttpStatusCode.OK);
            }
            else
            {
                return Request.CreateErrorResponse(HttpStatusCode.BadRequest, ModelState);
            }
        }
    }
}
```

Model validation does not guarantee that client data is safe. Additional validation might be needed in other layers of the application. (For example, the data layer might enforce foreign key constraints.) The tutorial Using Web API with Entity Framework explores some of these issues.

"Under-Posting": Under-posting happens when the client leaves out some properties. For example, suppose the client sends the following:

```
{"Id":4, "Name":"Gizmo"}
```

Here, the client did not specify values for `Price` or `Weight`. The JSON formatter assigns a default value of zero to the missing properties.

The model state is valid, because zero is a valid value for these properties. Whether this is a problem depends on your scenario. For example, in an update operation, you might want to distinguish between "zero" and "not set." To force clients to set a value, make the property nullable and set the **Required** attribute:

```
[Required]
public decimal? Price { get; set; }
```

"Over-Posting": A client can also send *more* data than you expected. For example:

```
{"Id":4, "Name":"Gizmo", "Color":"Blue"}
```

Here, the JSON includes a property ("Color") that does not exist in the `Product` model. In this case, the JSON formatter simply ignores this value. (The XML formatter does the same.) Over-posting causes problems if your model has properties that you intended to be read-only. For example:

```
public class UserProfile
{
    public string Name { get; set; }
    public Uri Blog { get; set; }
    public bool IsAdmin { get; set; }  // uh-oh!
}
```

You don't want users to update the `IsAdmin` property and elevate themselves to administrators! The safest strategy is to use a model class that exactly matches what the client is allowed to send:

```
public class UserProfileDTO
{
    public string Name { get; set; }
    public Uri Blog { get; set; }
    // Leave out "IsAdmin"
}
```

NOTE

Brad Wilson's blog post "Input Validation vs. Model Validation in ASP.NET MVC" has a good discussion of under-posting and over-posting. Although the post is about ASP.NET MVC 2, the issues are still relevant to Web API.

Handling Validation Errors

Web API does not automatically return an error to the client when validation fails. It is up to the controller action to check the model state and respond appropriately.

You can also create an action filter to check the model state before the controller action is invoked. The following code shows an example:

```
using System.Collections.Generic;
using System.Linq;
using System.Net;
using System.Net.Http;
using System.Web.Http.Controllers;
using System.Web.Http.Filters;
using System.Web.Http.ModelBinding;

namespace MyApi.Filters
{
    public class ValidateModelAttribute : ActionFilterAttribute
    {
        public override void OnActionExecuting(HttpActionContext actionContext)
        {
            if (actionContext.ModelState.IsValid == false)
            {
                actionContext.Response = actionContext.Request.CreateErrorResponse(
                    HttpStatusCode.BadRequest, actionContext.ModelState);
            }
        }
    }
}
```

If model validation fails, this filter returns an HTTP response that contains the validation errors. In that case, the

controller action is not invoked.

```
HTTP/1.1 400 Bad Request
Content-Type: application/json; charset=utf-8
Date: Tue, 16 Jul 2013 21:02:29 GMT
Content-Length: 331

{
  "Message": "The request is invalid.",
  "ModelState": {
    "product": [
      "Required property 'Name' not found in JSON. Path '', line 1, position 17."
    ],
    "product.Name": [
      "The Name field is required."
    ],
    "product.Weight": [
      "The field Weight must be between 0 and 999."
    ]
  }
}
```

To apply this filter to all Web API controllers, add an instance of the filter to the **HttpConfiguration.Filters** collection during configuration:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.Filters.Add(new ValidateModelAttribute());

        // ...
    }
}
```

Another option is to set the filter as an attribute on individual controllers or controller actions:

```
public class ProductsController : ApiController
{
    [ValidateModel]
    public HttpResponseMessage Post(Product product)
    {
        // ...
    }
}
```

Parameter Binding in ASP.NET Web API

2/20/2020 • 12 minutes to read • Edit Online

by Mike Wasson

Consider using ASP.NET Core web API. It has the following advantages over ASP.NET 4.x Web API:

- ASP.NET Core is an open-source, cross-platform framework for building modern, cloud-based web apps on Windows, macOS, and Linux.
- The ASP.NET Core MVC controllers and web API controllers are unified.
- Architected for testability.
- Ability to develop and run on Windows, macOS, and Linux.
- Open-source and community-focused.
- Integration of modern, client-side frameworks and development workflows.
- A cloud-ready, environment-based configuration system.
- Built-in dependency injection.
- A lightweight, high-performance, and modular HTTP request pipeline.
- Ability to host on Kestrel, IIS, HTTP.sys, Nginx, Apache, and Docker.
- Side-by-side versioning.
- Tooling that simplifies modern web development.

This article describes how Web API binds parameters, and how you can customize the binding process. When Web API calls a method on a controller, it must set values for the parameters, a process called *binding*.

By default, Web API uses the following rules to bind parameters:

- If the parameter is a "simple" type, Web API tries to get the value from the URI. Simple types include the .NET primitive types (**int**, **bool**, **double**, and so forth), plus **TimeSpan**, **DateTime**, **Guid**, **decimal**, and **string**, *plus* any type with a type converter that can convert from a string. (More about type converters later.)
- For complex types, Web API tries to read the value from the message body, using a media-type formatter.

For example, here is a typical Web API controller method:

```
HttpResponseMessage Put(int id, Product item) { ... }
```

The *id* parameter is a "simple" type, so Web API tries to get the value from the request URI. The *item* parameter is a complex type, so Web API uses a media-type formatter to read the value from the request body.

To get a value from the URI, Web API looks in the route data and the URI query string. The route data is populated when the routing system parses the URI and matches it to a route. For more information, see Routing and Action Selection.

In the rest of this article, I'll show how you can customize the model binding process. For complex types, however, consider using media-type formatters whenever possible. A key principle of HTTP is that resources are sent in the message body, using content negotiation to specify the representation of the resource. Media-type formatters were designed for exactly this purpose.

Using [FromUri]

To force Web API to read a complex type from the URI, add the **[FromUri]** attribute to the parameter. The

following example defines a `GeoPoint` type, along with a controller method that gets the `GeoPoint` from the URI.

```
public class GeoPoint
{
    public double Latitude { get; set; }
    public double Longitude { get; set; }
}

public ValuesController : ApiController
{
    public HttpResponseMessage Get([FromUri] GeoPoint location) { ... }
}
```

The client can put the Latitude and Longitude values in the query string and Web API will use them to construct a `GeoPoint`. For example:

`http://localhost/api/values/?Latitude=47.678558&Longitude=-122.130989`

Using [FromBody]

To force Web API to read a simple type from the request body, add the **[FromBody]** attribute to the parameter:

```
public HttpResponseMessage Post([FromBody] string name) { ... }
```

In this example, Web API will use a media-type formatter to read the value of *name* from the request body. Here is an example client request.

```
POST http://localhost:5076/api/values HTTP/1.1
User-Agent: Fiddler
Host: localhost:5076
Content-Type: application/json
Content-Length: 7

"Alice"
```

When a parameter has [FromBody], Web API uses the Content-Type header to select a formatter. In this example, the content type is "application/json" and the request body is a raw JSON string (not a JSON object).

At most one parameter is allowed to read from the message body. So this will not work:

```
// Caution: Will not work!
public HttpResponseMessage Post([FromBody] int id, [FromBody] string name) { ... }
```

The reason for this rule is that the request body might be stored in a non-buffered stream that can only be read once.

Type Converters

You can make Web API treat a class as a simple type (so that Web API will try to bind it from the URI) by creating a **TypeConverter** and providing a string conversion.

The following code shows a `GeoPoint` class that represents a geographical point, plus a **TypeConverter** that converts from strings to `GeoPoint` instances. The `GeoPoint` class is decorated with a **[TypeConverter]** attribute to specify the type converter. (This example was inspired by Mike Stall's blog post How to bind to custom objects in action signatures in MVC/WebAPI.)

```
[TypeConverter(typeof(GeoPointConverter))]
public class GeoPoint
{
    public double Latitude { get; set; }
    public double Longitude { get; set; }

    public static bool TryParse(string s, out GeoPoint result)
    {
        result = null;

        var parts = s.Split(',');
        if (parts.Length != 2)
        {
            return false;
        }

        double latitude, longitude;
        if (double.TryParse(parts[0], out latitude) &&
            double.TryParse(parts[1], out longitude))
        {
            result = new GeoPoint() { Longitude = longitude, Latitude = latitude };
            return true;
        }
        return false;
    }
}

class GeoPointConverter : TypeConverter
{
    public override bool CanConvertFrom(ITypeDescriptorContext context, Type sourceType)
    {
        if (sourceType == typeof(string))
        {
            return true;
        }
        return base.CanConvertFrom(context, sourceType);
    }

    public override object ConvertFrom(ITypeDescriptorContext context,
        CultureInfo culture, object value)
    {
        if (value is string)
        {
            GeoPoint point;
            if (GeoPoint.TryParse((string)value, out point))
            {
                return point;
            }
        }
        return base.ConvertFrom(context, culture, value);
    }
}
```

Now Web API will treat `GeoPoint` as a simple type, meaning it will try to bind `GeoPoint` parameters from the URI. You don't need to include **[FromUri]** on the parameter.

```
public HttpResponseMessage Get(GeoPoint location) { ... }
```

The client can invoke the method with a URI like this:

`http://localhost/api/values/?location=47.678558,-122.130989`

Model Binders

A more flexible option than a type converter is to create a custom model binder. With a model binder, you have access to things like the HTTP request, the action description, and the raw values from the route data.

To create a model binder, implement the **IModelBinder** interface. This interface defines a single method, **BindModel**:

```
bool BindModel(HttpActionContext actionContext, ModelBindingContext bindingContext);
```

Here is a model binder for `GeoPoint` objects.

```
public class GeoPointModelBinder : IModelBinder
{
    // List of known locations.
    private static ConcurrentDictionary<string, GeoPoint> _locations
        = new ConcurrentDictionary<string, GeoPoint>(StringComparer.OrdinalIgnoreCase);

    static GeoPointModelBinder()
    {
        _locations["redmond"] = new GeoPoint() { Latitude = 47.67856, Longitude = -122.131 };
        _locations["paris"] = new GeoPoint() { Latitude = 48.856930, Longitude = 2.3412 };
        _locations["tokyo"] = new GeoPoint() { Latitude = 35.683208, Longitude = 139.80894 };
    }

    public bool BindModel(HttpActionContext actionContext, ModelBindingContext bindingContext)
    {
        if (bindingContext.ModelType != typeof(GeoPoint))
        {
            return false;
        }

        ValueProviderResult val = bindingContext.ValueProvider.GetValue(
            bindingContext.ModelName);
        if (val == null)
        {
            return false;
        }

        string key = val.RawValue as string;
        if (key == null)
        {
            bindingContext.ModelState.AddModelError(
                bindingContext.ModelName, "Wrong value type");
            return false;
        }

        GeoPoint result;
        if (_locations.TryGetValue(key, out result) || GeoPoint.TryParse(key, out result))
        {
            bindingContext.Model = result;
            return true;
        }

        bindingContext.ModelState.AddModelError(
            bindingContext.ModelName, "Cannot convert value to GeoPoint");
        return false;
    }
}
```

A model binder gets raw input values from a *value provider*. This design separates two distinct functions:

- The value provider takes the HTTP request and populates a dictionary of key-value pairs.
- The model binder uses this dictionary to populate the model.

The default value provider in Web API gets values from the route data and the query string. For example, if the URI is `http://localhost/api/values/1?location=48,-122`, the value provider creates the following key-value pairs:

- id = "1"
- location = "48,122"

(I'm assuming the default route template, which is "api/{controller}/{id}".)

The name of the parameter to bind is stored in the **ModelBindingContext.ModelName** property. The model binder looks for a key with this value in the dictionary. If the value exists and can be converted into a `GeoPoint`, the model binder assigns the bound value to the **ModelBindingContext.Model** property.

Notice that the model binder is not limited to a simple type conversion. In this example, the model binder first looks in a table of known locations, and if that fails, it uses type conversion.

Setting the Model Binder

There are several ways to set a model binder. First, you can add a **[ModelBinder]** attribute to the parameter.

```
public HttpResponseMessage Get([ModelBinder(typeof(GeoPointModelBinder))] GeoPoint location)
```

You can also add a **[ModelBinder]** attribute to the type. Web API will use the specified model binder for all parameters of that type.

```
[ModelBinder(typeof(GeoPointModelBinder))]
public class GeoPoint
{
    // ....
}
```

Finally, you can add a model-binder provider to the **HttpConfiguration**. A model-binder provider is simply a factory class that creates a model binder. You can create a provider by deriving from the ModelBinderProvider class. However, if your model binder handles a single type, it's easier to use the built-in **SimpleModelBinderProvider**, which is designed for this purpose. The following code shows how to do this.

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        var provider = new SimpleModelBinderProvider(
            typeof(GeoPoint), new GeoPointModelBinder());
        config.Services.Insert(typeof(ModelBinderProvider), 0, provider);

        // ...
    }
}
```

With a model-binding provider, you still need to add the **[ModelBinder]** attribute to the parameter, to tell Web API that it should use a model binder and not a media-type formatter. But now you don't need to specify the type of model binder in the attribute:

```
public HttpResponseMessage Get([ModelBinder] GeoPoint location) { ... }
```

Value Providers

I mentioned that a model binder gets values from a value provider. To write a custom value provider, implement

the **IValueProvider** interface. Here is an example that pulls values from the cookies in the request:

```
public class CookieValueProvider : IValueProvider
{
    private Dictionary<string, string> _values;

    public CookieValueProvider(HttpActionContext actionContext)
    {
        if (actionContext == null)
        {
            throw new ArgumentNullException("actionContext");
        }

        _values = new Dictionary<string, string>(StringComparer.OrdinalIgnoreCase);
        foreach (var cookie in actionContext.Request.Headers.GetCookies())
        {
            foreach (CookieState state in cookie.Cookies)
            {
                _values[state.Name] = state.Value;
            }
        }
    }

    public bool ContainsPrefix(string prefix)
    {
        return _values.Keys.Contains(prefix);
    }

    public ValueProviderResult GetValue(string key)
    {
        string value;
        if (_values.TryGetValue(key, out value))
        {
            return new ValueProviderResult(value, value, CultureInfo.InvariantCulture);
        }
        return null;
    }
}
```

You also need to create a value provider factory by deriving from the **ValueProviderFactory** class.

```
public class CookieValueProviderFactory : ValueProviderFactory
{
    public override IValueProvider GetValueProvider(HttpActionContext actionContext)
    {
        return new CookieValueProvider(actionContext);
    }
}
```

Add the value provider factory to the **HttpConfiguration** as follows.

```
public static void Register(HttpConfiguration config)
{
    config.Services.Add(typeof(ValueProviderFactory), new CookieValueProviderFactory());

    // ...
}
```

Web API composes all of the value providers, so when a model binder calls **ValueProvider.GetValue**, the model binder receives the value from the first value provider that is able to produce it.

Alternatively, you can set the value provider factory at the parameter level by using the **ValueProvider** attribute,

as follows:

```
public HttpResponseMessage Get(
    [ValueProvider(typeof(CookieValueProviderFactory))] GeoPoint location)
```

This tells Web API to use model binding with the specified value provider factory, and not to use any of the other registered value providers.

HttpParameterBinding

Model binders are a specific instance of a more general mechanism. If you look at the **[ModelBinder]** attribute, you will see that it derives from the abstract **ParameterBindingAttribute** class. This class defines a single method, **GetBinding**, which returns an **HttpParameterBinding** object:

```
public abstract class ParameterBindingAttribute : Attribute
{
    public abstract HttpParameterBinding GetBinding(HttpParameterDescriptor parameter);
}
```

An **HttpParameterBinding** is responsible for binding a parameter to a value. In the case of **[ModelBinder]**, the attribute returns an **HttpParameterBinding** implementation that uses an **IModelBinder** to perform the actual binding. You can also implement your own **HttpParameterBinding**.

For example, suppose you want to get ETags from `if-match` and `if-none-match` headers in the request. We'll start by defining a class to represent ETags.

```
public class ETag
{
    public string Tag { get; set; }
}
```

We'll also define an enumeration to indicate whether to get the ETag from the `if-match` header or the `if-none-match` header.

```
public enum ETagMatch
{
    IfMatch,
    IfNoneMatch
}
```

Here is an **HttpParameterBinding** that gets the ETag from the desired header and binds it to a parameter of type ETag:

```
public class ETagParameterBinding : HttpParameterBinding
{
    ETagMatch _match;

    public ETagParameterBinding(HttpParameterDescriptor parameter, ETagMatch match)
        : base(parameter)
    {
        _match = match;
    }

    public override Task ExecuteBindingAsync(ModelMetadataProvider metadataProvider,
        HttpActionContext actionContext, CancellationToken cancellationToken)
    {
        EntityTagHeaderValue etagHeader = null;
        switch (_match)
        {
            case ETagMatch.IfNoneMatch:
                etagHeader = actionContext.Request.Headers.IfNoneMatch.FirstOrDefault();
                break;

            case ETagMatch.IfMatch:
                etagHeader = actionContext.Request.Headers.IfMatch.FirstOrDefault();
                break;
        }

        ETag etag = null;
        if (etagHeader != null)
        {
            etag = new ETag { Tag = etagHeader.Tag };
        }
        actionContext.ActionArguments[Descriptor.ParameterName] = etag;

        var tsc = new TaskCompletionSource<object>();
        tsc.SetResult(null);
        return tsc.Task;
    }
}
```

The **ExecuteBindingAsync** method does the binding. Within this method, add the bound parameter value to the **ActionArgument** dictionary in the **HttpActionContext**.

> **NOTE**
>
> If your **ExecuteBindingAsync** method reads the body of the request message, override the **WillReadBody** property to return true. The request body might be an unbuffered stream that can only be read once, so Web API enforces a rule that at most one binding can read the message body.

To apply a custom **HttpParameterBinding**, you can define an attribute that derives from **ParameterBindingAttribute**. For `ETagParameterBinding`, we'll define two attributes, one for `if-match` headers and one for `if-none-match` headers. Both derive from an abstract base class.

```
public abstract class ETagMatchAttribute : ParameterBindingAttribute
{
    private ETagMatch _match;

    public ETagMatchAttribute(ETagMatch match)
    {
        _match = match;
    }

    public override HttpParameterBinding GetBinding(HttpParameterDescriptor parameter)
    {
        if (parameter.ParameterType == typeof(ETag))
        {
            return new ETagParameterBinding(parameter, _match);
        }
        return parameter.BindAsError("Wrong parameter type");
    }
}

public class IfMatchAttribute : ETagMatchAttribute
{
    public IfMatchAttribute()
        : base(ETagMatch.IfMatch)
    {
    }
}

public class IfNoneMatchAttribute : ETagMatchAttribute
{
    public IfNoneMatchAttribute()
        : base(ETagMatch.IfNoneMatch)
    {
    }
}
```

Here is a controller method that uses the `[IfNoneMatch]` attribute.

```
public HttpResponseMessage Get([IfNoneMatch] ETag etag) { ... }
```

Besides **ParameterBindingAttribute**, there is another hook for adding a custom **HttpParameterBinding**. On the **HttpConfiguration** object, the **ParameterBindingRules** property is a collection of anonymous functions of type (**HttpParameterDescriptor** -> **HttpParameterBinding**). For example, you could add a rule that any ETag parameter on a GET method uses `ETagParameterBinding` with `if-none-match`:

```
config.ParameterBindingRules.Add(p =>
{
    if (p.ParameterType == typeof(ETag) &&
        p.ActionDescriptor.SupportedHttpMethods.Contains(HttpMethod.Get))
    {
        return new ETagParameterBinding(p, ETagMatch.IfNoneMatch);
    }
    else
    {
        return null;
    }
});
```

The function should return `null` for parameters where the binding is not applicable.

IActionValueBinder

The entire parameter-binding process is controlled by a pluggable service, **IActionValueBinder**. The default implementation of **IActionValueBinder** does the following:

1. Look for a **ParameterBindingAttribute** on the parameter. This includes **[FromBody]**, **[FromUri]**, and **[ModelBinder]**, or custom attributes.
2. Otherwise, look in **HttpConfiguration.ParameterBindingRules** for a function that returns a non-null **HttpParameterBinding**.
3. Otherwise, use the default rules that I described previously.
   - If the parameter type is "simple"or has a type converter, bind from the URI. This is equivalent to putting the **[FromUri]** attribute on the parameter.
   - Otherwise, try to read the parameter from the message body. This is equivalent to putting **[FromBody]** on the parameter.

If you wanted, you could replace the entire **IActionValueBinder** service with a custom implementation.

Exception Handling in ASP.NET Web API

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

This article describes error and exception handling in ASP.NET Web API.

- HttpResponseException
- Exception Filters
- Registering Exception Filters
- HttpError

HttpResponseException

What happens if a Web API controller throws an uncaught exception? By default, most exceptions are translated into an HTTP response with status code 500, Internal Server Error.

The **HttpResponseException** type is a special case. This exception returns any HTTP status code that you specify in the exception constructor. For example, the following method returns 404, Not Found, if the *id* parameter is not valid.

```
public Product GetProduct(int id)
{
    Product item = repository.Get(id);
    if (item == null)
    {
        throw new HttpResponseException(HttpStatusCode.NotFound);
    }
    return item;
}
```

For more control over the response, you can also construct the entire response message and include it with the **HttpResponseException**:

```
public Product GetProduct(int id)
{
    Product item = repository.Get(id);
    if (item == null)
    {
        var resp = new HttpResponseMessage(HttpStatusCode.NotFound)
        {
            Content = new StringContent(string.Format("No product with ID = {0}", id)),
            ReasonPhrase = "Product ID Not Found"
        };
        throw new HttpResponseException(resp);
    }
    return item;
}
```

Exception Filters

You can customize how Web API handles exceptions by writing an *exception filter*. An exception filter is executed when a controller method throws any unhandled exception that is *not* an **HttpResponseException** exception.

The **HttpResponseException** type is a special case, because it is designed specifically for returning an HTTP response.

Exception filters implement the **System.Web.Http.Filters.IExceptionFilter** interface. The simplest way to write an exception filter is to derive from the **System.Web.Http.Filters.ExceptionFilterAttribute** class and override the **OnException** method.

> **NOTE**
> Exception filters in ASP.NET Web API are similar to those in ASP.NET MVC. However, they are declared in a separate namespace and function separately. In particular, the **HandleErrorAttribute** class used in MVC does not handle exceptions thrown by Web API controllers.

Here is a filter that converts **NotImplementedException** exceptions into HTTP status code 501, Not Implemented:

```
namespace ProductStore.Filters
{
    using System;
    using System.Net;
    using System.Net.Http;
    using System.Web.Http.Filters;

    public class NotImplExceptionFilterAttribute : ExceptionFilterAttribute
    {
        public override void OnException(HttpActionExecutedContext context)
        {
            if (context.Exception is NotImplementedException)
            {
                context.Response = new HttpResponseMessage(HttpStatusCode.NotImplemented);
            }
        }
    }
}
```

The **Response** property of the **HttpActionExecutedContext** object contains the HTTP response message that will be sent to the client.

Registering Exception Filters

There are several ways to register a Web API exception filter:

- By action
- By controller
- Globally

To apply the filter to a specific action, add the filter as an attribute to the action:

```
public class ProductsController : ApiController
{
    [NotImplExceptionFilter]
    public Contact GetContact(int id)
    {
        throw new NotImplementedException("This method is not implemented");
    }
}
```

To apply the filter to all of the actions on a controller, add the filter as an attribute to the controller class:

```
[NotImplExceptionFilter]
public class ProductsController : ApiController
{
    // ...
}
```

To apply the filter globally to all Web API controllers, add an instance of the filter to the **GlobalConfiguration.Configuration.Filters** collection. Exception filters in this collection apply to any Web API controller action.

```
GlobalConfiguration.Configuration.Filters.Add(
    new ProductStore.NotImplExceptionFilterAttribute());
```

If you use the "ASP.NET MVC 4 Web Application" project template to create your project, put your Web API configuration code inside the `WebApiConfig` class, which is located in the App_Start folder:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.Filters.Add(new ProductStore.NotImplExceptionFilterAttribute());

        // Other configuration code...
    }
}
```

HttpError

The **HttpError** object provides a consistent way to return error information in the response body. The following example shows how to return HTTP status code 404 (Not Found) with an **HttpError** in the response body.

```
public HttpResponseMessage GetProduct(int id)
{
    Product item = repository.Get(id);
    if (item == null)
    {
        var message = string.Format("Product with id = {0} not found", id);
        return Request.CreateErrorResponse(HttpStatusCode.NotFound, message);
    }
    else
    {
        return Request.CreateResponse(HttpStatusCode.OK, item);
    }
}
```

CreateErrorResponse is an extension method defined in the **System.Net.Http.HttpRequestMessageExtensions** class. Internally, **CreateErrorResponse** creates an **HttpError** instance and then creates an **HttpResponseMessage** that contains the **HttpError**.

In this example, if the method is successful, it returns the product in the HTTP response. But if the requested product is not found, the HTTP response contains an **HttpError** in the request body. The response might look like the following:

```
HTTP/1.1 404 Not Found
Content-Type: application/json; charset=utf-8
Date: Thu, 09 Aug 2012 23:27:18 GMT
Content-Length: 51

{
  "Message": "Product with id = 12 not found"
}
```

Notice that the **HttpError** was serialized to JSON in this example. One advantage of using **HttpError** is that it goes through the same content-negotiation and serialization process as any other strongly-typed model.

HttpError and Model Validation

For model validation, you can pass the model state to **CreateErrorResponse**, to include the validation errors in the response:

```
public HttpResponseMessage PostProduct(Product item)
{
    if (!ModelState.IsValid)
    {
        return Request.CreateErrorResponse(HttpStatusCode.BadRequest, ModelState);
    }

    // Implementation not shown...
}
```

This example might return the following response:

```
HTTP/1.1 400 Bad Request
Content-Type: application/json; charset=utf-8
Content-Length: 320

{
  "Message": "The request is invalid.",
  "ModelState": {
    "item": [
      "Required property 'Name' not found in JSON. Path '', line 1, position 14."
    ],
    "item.Name": [
      "The Name field is required."
    ],
    "item.Price": [
      "The field Price must be between 0 and 999."
    ]
  }
}
```

For more information about model validation, see Model Validation in ASP.NET Web API.

Using HttpError with HttpResponseException

The previous examples return an **HttpResponseMessage** message from the controller action, but you can also use **HttpResponseException** to return an **HttpError**. This lets you return a strongly-typed model in the normal success case, while still returning **HttpError** if there is an error:

```
public Product GetProduct(int id)
{
    Product item = repository.Get(id);
    if (item == null)
    {
        var message = string.Format("Product with id = {0} not found", id);
        throw new HttpResponseException(
            Request.CreateErrorResponse(HttpStatusCode.NotFound, message));
    }
    else
    {
        return item;
    }
}
```

Global Error Handling in ASP.NET Web API 2

4/6/2020 • 9 minutes to read • Edit Online

by David Matson, Rick Anderson

This topic provides an overview of global error handling in ASP.NET Web API 2 for ASP.NET 4.x. Today there's no easy way in Web API to log or handle errors globally. Some unhandled exceptions can be processed via exception filters, but there are a number of cases that exception filters can't handle. For example:

1. Exceptions thrown from controller constructors.
2. Exceptions thrown from message handlers.
3. Exceptions thrown during routing.
4. Exceptions thrown during response content serialization.

We want to provide a simple, consistent way to log and handle (where possible) these exceptions.

There are two major cases for handling exceptions, the case where we are able to send an error response and the case where all we can do is log the exception. An example for the latter case is when an exception is thrown in the middle of streaming response content; in that case it is too late to send a new response message since the status code, headers, and partial content have already gone across the wire, so we simply abort the connection. Even though the exception can't be handled to produce a new response message, we still support logging the exception. In cases where we can detect an error, we can return an appropriate error response as shown in the following:

```
public IHttpActionResult GetProduct(int id)
{
    var product = products.FirstOrDefault((p) => p.Id == id);
    if (product == null)
    {
        return NotFound();
    }
    return Ok(product);
}
```

Existing Options

In addition to exception filters, message handlers can be used today to observe all 500-level responses, but acting on those responses is difficult, as they lack context about the original error. Message handlers also have some of the same limitations as exception filters regarding the cases they can handle. While Web API does have tracing infrastructure that captures error conditions the tracing infrastructure is for diagnostics purposes and is not designed or suited for running in production environments. Global exception handling and logging should be services that can run during production and be plugged into existing monitoring solutions (for example, ELMAH).

Solution Overview

We provide two new user-replaceable services, IExceptionLogger and IExceptionHandler, to log and handle unhandled exceptions. The services are very similar, with two main differences:

1. We support registering multiple exception loggers but only a single exception handler.
2. Exception loggers always get called, even if we're about to abort the connection. Exception handlers only get called when we're still able to choose which response message to send.

Both services provide access to an exception context containing relevant information from the point where the exception was detected, particularly the HttpRequestMessage, the HttpRequestContext, the thrown exception and the exception source (details below).

Design Principles

1. **No breaking changes** Because this functionality is being added in a minor release, one important constraint impacting the solution is that there be no breaking changes, either to type contracts or to behavior. This constraint ruled out some cleanup we would like to have done in terms of existing catch blocks turning exceptions into 500 responses. This additional cleanup is something we might consider for a subsequent major release. If this is important to you please vote on it at ASP.NET Web API user voice.
2. **Maintaining consistency with Web API constructs** Web API's filter pipeline is a great way to handle cross-cutting concerns with the flexibility of applying the logic at an action-specific, controller-specific or global scope. Filters, including exception filters, always have action and controller contexts, even when registered at the global scope. That contract makes sense for filters, but it means that exception filters, even globally scoped ones, aren't a good fit for some exception handling cases, such as exceptions from message handlers, where no action or controller context exists. If we want to use the flexible scoping afforded by filters for exception handling, we still need exception filters. But if we need to handle exception outside of a controller context, we also need a separate construct for full global error handling (something without the controller context and action context constraints).

When to Use

- Exception loggers are the solution to seeing all unhandled exception caught by Web API.
- Exception handlers are the solution for customizing all possible responses to unhandled exceptions caught by Web API.
- Exception filters are the easiest solution for processing the subset unhandled exceptions related to a specific action or controller.

Service Details

The exception logger and handler service interfaces are simple async methods taking the respective contexts:

```
public interface IExceptionLogger
{
   Task LogAsync(ExceptionLoggerContext context,
                 CancellationToken cancellationToken);
}

public interface IExceptionHandler
{
   Task HandleAsync(ExceptionHandlerContext context,
                    CancellationToken cancellationToken);
}
```

We also provide base classes for both of these interfaces. Overriding the core (sync or async) methods is all that is required to log or handle at the recommended times. For logging, the `ExceptionLogger` base class will ensure that the core logging method is only called once for each exception (even if it later propagates further up the call stack and is caught again). The `ExceptionHandler` base class will call the core handling method only for exceptions at the top of the call stack, ignoring legacy nested catch blocks. (Simplified versions of these base classes are in the appendix below.) Both `IExceptionLogger` and `IExceptionHandler` receive information about the exception via an `ExceptionContext`.

```
public class ExceptionContext
{
   public Exception Exception { get; set; }

   public HttpRequestMessage Request { get; set; }

   public HttpRequestContext RequestContext { get; set; }

   public HttpControllerContext ControllerContext { get; set; }

   public HttpActionContext ActionContext { get; set; }

   public HttpResponseMessage Response { get; set; }

   public string CatchBlock { get; set; }

   public bool IsTopLevelCatchBlock { get; set; }
}
```

When the framework calls an exception logger or an exception handler, it will always provide an `Exception` and a `Request`. Except for unit testing, it will also always provide a `RequestContext`. It will rarely provide a `ControllerContext` and `ActionContext` (only when calling from the catch block for exception filters). It will very rarely provide a `Response` (only in certain IIS cases when in the middle of trying to write the response). Note that because some of these properties may be `null` it is up to the consumer to check for `null` before accessing members of the exception class. `CatchBlock` is a string indicating which catch block saw the exception. The catch block strings are as follows:

- HttpServer (SendAsync method)
- HttpControllerDispatcher (SendAsync method)
- HttpBatchHandler (SendAsync method)
- IExceptionFilter (ApiController's processing of the exception filter pipeline in ExecuteAsync)
- OWIN host:
  - HttpMessageHandlerAdapter.BufferResponseContentAsync (for buffering output)
  - HttpMessageHandlerAdapter.CopyResponseContentAsync (for streaming output)
- Web host:
  - HttpControllerHandler.WriteBufferedResponseContentAsync (for buffering output)
  - HttpControllerHandler.WriteStreamedResponseContentAsync (for streaming output)
  - HttpControllerHandler.WriteErrorResponseContentAsync (for failures in error recovery under buffered output mode)

The list of catch block strings is also available via static readonly properties. (The core catch block string are on the static ExceptionCatchBlocks; the remainder appear on one static class each for OWIN and web host). `IsTopLevelCatchBlock` is helpful for following the recommended pattern of handling exceptions only at the top of the call stack. Rather than turning exceptions into 500 responses anywhere a nested catch block occurs, an exception handler can let exceptions propagate until they are about to be seen by the host.

In addition to the `ExceptionContext`, a logger gets one more piece of information via the full `ExceptionLoggerContext`:

```
public class ExceptionLoggerContext
{
   public ExceptionContext ExceptionContext { get; set; }
   public bool CanBeHandled { get; set; }
}
```

The second property, `CanBeHandled`, allows a logger to identify an exception that cannot be handled. When the connection is about to be aborted and no new response message can be sent, the loggers will be called but the handler will *not* be called, and the loggers can identify this scenario from this property.

In additional to the `ExceptionContext`, a handler gets one more property it can set on the full `ExceptionHandlerContext` to handle the exception:

```
public class ExceptionHandlerContext
{
   public ExceptionContext ExceptionContext { get; set; }
   public IHttpActionResult Result { get; set; }
}
```

An exception handler indicates that it has handled an exception by setting the `Result` property to an action result (for example, an ExceptionResult, InternalServerErrorResult, StatusCodeResult, or a custom result). If the `Result` property is null, the exception is unhandled and the original exception will be re-thrown.

For exceptions at the top of the call stack, we took an extra step to ensure the response is appropriate for API callers. If the exception propagates up to the host, the caller would see the yellow screen of death or some other host provided response which is typically HTML and not usually an appropriate API error response. In these cases, the Result starts out non-null, and only if a custom exception handler explicitly sets it back to `null` (unhandled) will the exception propagate to the host. Setting `Result` to `null` in such cases can be useful for two scenarios:

1. OWIN hosted Web API with custom exception handling middleware registered before/outside Web API.
2. Local debugging via a browser, where the yellow screen of death is actually a helpful response for an unhandled exception.

For both exception loggers and exception handlers, we don't do anything to recover if the logger or handler itself throws an exception. (Other than letting the exception propagate, leave feedback at the bottom of this page if you have a better approach.) The contract for exception loggers and handlers is that they should not let exceptions propagate up to their callers; otherwise, the exception will just propagate, often all the way to the host resulting in an HTML error (like ASP.NET's yellow screen) being sent back to the client (which usually isn't the preferred option for API callers that expect JSON or XML).

Examples

Tracing Exception Logger

The exception logger below sends exception data to configured Trace sources (including the Debug output window in Visual Studio).

```
class TraceExceptionLogger : ExceptionLogger
{
    public override void LogCore(ExceptionLoggerContext context)
    {
        Trace.TraceError(context.ExceptionContext.Exception.ToString());
    }
}
```

Custom Error Message Exception Handler

The exception handler below produces a custom error response to clients, including an email address for contacting support.

```
class OopsExceptionHandler : ExceptionHandler
{
    public override void HandleCore(ExceptionHandlerContext context)
    {
        context.Result = new TextPlainErrorResult
        {
            Request = context.ExceptionContext.Request,
            Content = "Oops! Sorry! Something went wrong." +
                      "Please contact support@contoso.com so we can try to fix it."
        };
    }

    private class TextPlainErrorResult : IHttpActionResult
    {
        public HttpRequestMessage Request { get; set; }

        public string Content { get; set; }

        public Task<HttpResponseMessage> ExecuteAsync(CancellationToken cancellationToken)
        {
            HttpResponseMessage response =
                              new HttpResponseMessage(HttpStatusCode.InternalServerError);
            response.Content = new StringContent(Content);
            response.RequestMessage = Request;
            return Task.FromResult(response);
        }
    }
}
```

Registering Exception Filters

If you use the "ASP.NET MVC 4 Web Application" project template to create your project, put your Web API configuration code inside the `WebApiConfig` class, in the *App_Start* folder:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.Filters.Add(new ProductStore.NotImplExceptionFilterAttribute());

        // Other configuration code...
    }
}
```

Appendix: Base Class Details

```
public class ExceptionLogger : IExceptionLogger
{
    public virtual Task LogAsync(ExceptionLoggerContext context,
                                 CancellationToken cancellationToken)
    {
        if (!ShouldLog(context))
        {
            return Task.FromResult(0);
        }

        return LogAsyncCore(context, cancellationToken);
    }
```

```
    public virtual Task LogAsyncCore(ExceptionLoggerContext context,
                                     CancellationToken cancellationToken)
    {
        LogCore(context);
        return Task.FromResult(0);
    }

    public virtual void LogCore(ExceptionLoggerContext context)
    {
    }

    public virtual bool ShouldLog(ExceptionLoggerContext context)
    {
        IDictionary exceptionData = context.ExceptionContext.Exception.Data;

        if (!exceptionData.Contains("MS_LoggedBy"))
        {
            exceptionData.Add("MS_LoggedBy", new List<object>());
        }

        ICollection<object> loggedBy = ((ICollection<object>)exceptionData[LoggedByKey]);

        if (!loggedBy.Contains(this))
        {
            loggedBy.Add(this);
            return true;
        }
        else
        {
            return false;
        }
    }
}

public class ExceptionHandler : IExceptionHandler
{
    public virtual Task HandleAsync(ExceptionHandlerContext context,
                                    CancellationToken cancellationToken)
    {
        if (!ShouldHandle(context))
        {
            return Task.FromResult(0);
        }

        return HandleAsyncCore(context, cancellationToken);
    }

    public virtual Task HandleAsyncCore(ExceptionHandlerContext context,
                                        CancellationToken cancellationToken)
    {
        HandleCore(context);
        return Task.FromResult(0);
    }

    public virtual void HandleCore(ExceptionHandlerContext context)
    {
    }

    public virtual bool ShouldHandle(ExceptionHandlerContext context)
    {
        return context.ExceptionContext.IsOutermostCatchBlock;
    }
}
```

Tracing in ASP.NET Web API 2

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

When you are trying to debug a web-based application, there is no substitute for a good set of trace logs. This tutorial shows how to enable tracing in ASP.NET Web API. You can use this feature to trace what the Web API framework does before and after it invokes your controller. You can also use it to trace your own code.

Software versions used in the tutorial

- Visual Studio 2017 (also works with Visual Studio 2015)
- Web API 2
- Microsoft.AspNet.WebApi.Tracing

Enable System.Diagnostics Tracing in Web API

First, we'll create a new ASP.NET Web Application project. In Visual Studio, from the **File** menu, select **New** > **Project**. Under **Templates**, **Web**, select **ASP.NET Web Application**.

Choose the Web API project template.

From the **Tools** menu, select **NuGet Package Manager**, then **Package Manage Console**.

In the Package Manager Console window, type the following commands.

```
Install-Package Microsoft.AspNet.WebApi.Tracing
Update-Package Microsoft.AspNet.WebApi.WebHost
```

The first command installs the latest Web API tracing package. It also updates the core Web API packages. The second command updates the WebApi.WebHost package to the latest version.

> **NOTE**
> If you want to target a specific version of Web API, use the -Version flag when you install the tracing package.

Open the file WebApiConfig.cs in the App_Start folder. Add the following code to the **Register** method.

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        // New code
        config.EnableSystemDiagnosticsTracing();

        // Other configuration code not shown.
    }
}
```

This code adds the SystemDiagnosticsTraceWriter class to the Web API pipeline. The **SystemDiagnosticsTraceWriter** class writes traces to System.Diagnostics.Trace.

To see the traces, run the application in the debugger. In the browser, navigate to `/api/values`.

The trace statements are written to the Output window in Visual Studio. (From the **View** menu, select **Output**).

Because **SystemDiagnosticsTraceWriter** writes traces to **System.Diagnostics.Trace**, you can register additional trace listeners; for example, to write traces to a log file. For more information about trace writers, see the Trace Listeners topic on MSDN.

Configuring SystemDiagnosticsTraceWriter

The following code shows how to configure the trace writer.

```
SystemDiagnosticsTraceWriter traceWriter = config.EnableSystemDiagnosticsTracing();
traceWriter.IsVerbose = true;
traceWriter.MinimumLevel = TraceLevel.Debug;
```

There are two settings that you can control:

- IsVerbose: If false, each trace contains minimal information. If true, traces include more information.
- MinimumLevel: Sets the minimum trace level. Trace levels, in order, are Debug, Info, Warn, Error, and Fatal.

Adding Traces to Your Web API Application

Adding a trace writer gives you immediate access to the traces created by the Web API pipeline. You can also use the trace writer to trace your own code:

```
using System.Web.Http.Tracing;

public class ProductsController : ApiController
{
    public HttpResponseMessage GetAllProducts()
    {
        Configuration.Services.GetTraceWriter().Info(
            Request, "ProductsController", "Get the list of products.");

        // ...
    }
}
```

To get the trace writer, call **HttpConfiguration.Services.GetTraceWriter**. From a controller, this method is accessible through the **ApiController.Configuration** property.

To write a trace, you can call the **ITraceWriter.Trace** method directly, but the ITraceWriterExtensions class defines some extension methods that are more friendly. For example, the **Info** method shown above creates a trace with trace level **Info**.

Web API Tracing Infrastructure

This section describes how to write a custom trace writer for Web API.

The Microsoft.AspNet.WebApi.Tracing package is built on top of a more general tracing infrastructure in Web API. Instead of using Microsoft.AspNet.WebApi.Tracing, you can also plug in some other tracing/logging library, such as NLog or log4net.

To collect traces, implement the **ITraceWriter** interface. Here is a simple example:

```
public class SimpleTracer : ITraceWriter
{
    public void Trace(HttpRequestMessage request, string category, TraceLevel level,
        Action<TraceRecord> traceAction)
    {
        TraceRecord rec = new TraceRecord(request, category, level);
        traceAction(rec);
        WriteTrace(rec);
    }

    protected void WriteTrace(TraceRecord rec)
    {
        var message = string.Format("{0};{1};{2}",
            rec.Operator, rec.Operation, rec.Message);
        System.Diagnostics.Trace.WriteLine(message, rec.Category);
    }
}
```

The **ITraceWriter.Trace** method creates a trace. The caller specifies a category and trace level. The category can be any user-defined string. Your implementation of **Trace** should do the following:

1. Create a new **TraceRecord**. Initialize it with the request, category, and trace level, as shown. These values are provided by the caller.
2. Invoke the *traceAction* delegate. Inside this delegate, the caller is expected to fill in the rest of the **TraceRecord**.
3. Write the **TraceRecord**, using any logging technique that you like. The example shown here simply calls into **System.Diagnostics.Trace**.

Setting the Trace Writer

To enable tracing, you must configure Web API to use your **ITraceWriter** implementation. You do this through the **HttpConfiguration** object, as shown in the following code:

```
public static void Register(HttpConfiguration config)
{
    config.Services.Replace(typeof(ITraceWriter), new SimpleTracer());
}
```

Only one trace writer can be active. By default, Web API sets a "no-op" tracer that does nothing. (The "no-op" tracer exists so that tracing code does not have to check whether the trace writer is **null** before writing a trace.)

How Web API Tracing Works

Tracing in Web API uses a *facade* pattern: When tracing is enabled, Web API wraps various parts of the request pipeline with classes that perform trace calls.

For example, when selecting a controller, the pipeline uses the **IHttpControllerSelector** interface. With tracing enabled, the pipeline inserts a class that implements **IHttpControllerSelector** but calls through to the real implementation:

The benefits of this design include:

- If you do not add a trace writer, the tracing components are not instantiated and have no performance impact.
- If you replace default services such as **IHttpControllerSelector** with your own custom implementation, tracing is not affected, because tracing is done by the wrapper object.

You can also replace the entire Web API trace framework with your own custom framework, by replacing the default **ITraceManager** service:

```
config.Services.Replace(typeof(ITraceManager), new MyTraceManager());
```

Implement **ITraceManager.Initialize** to initialize your tracing system. Be aware that this replaces the *entire* trace framework, including all of the tracing code that is built into Web API.

Unit Testing ASP.NET Web API 2

2/20/2020 • 6 minutes to read • Edit Online

by Tom FitzMacken

Download Completed Project

This guidance and application demonstrate how to create simple unit tests for your Web API 2 application. This tutorial shows how to include a unit test project in your solution, and write test methods that check the returned values from a controller method.

This tutorial assumes you are familiar with the basic concepts of ASP.NET Web API. For an introductory tutorial, see Getting Started with ASP.NET Web API 2.

The unit tests in this topic are intentionally limited to simple data scenarios. For unit testing more advanced data scenarios, see Mocking Entity Framework when Unit Testing ASP.NET Web API 2.

Software versions used in the tutorial

- Visual Studio 2017
- Web API 2

In this topic

This topic contains the following sections:

- Prerequisites
- Download code
- Create application with unit test project
  - Add unit test project when creating the application
  - Add unit test project to an existing application
- Set up the Web API 2 application
- Install NuGet packages in test project
- Create tests
- Run tests

Prerequisites

Visual Studio 2017 Community, Professional or Enterprise edition

Download code

Download the completed project. The downloadable project includes unit test code for this topic and for the Mocking Entity Framework when Unit Testing ASP.NET Web API topic.

Create application with unit test project

You can either create a unit test project when creating your application or add a unit test project to an existing application. This tutorial shows both methods for creating a unit test project. To follow this tutorial, you can use either approach.

Add unit test project when creating the application

Create a new ASP.NET Web Application named **StoreApp**.

In the New ASP.NET Project windows, select the **Empty** template and add folders and core references for Web API. Select the **Add unit tests** option. The unit test project is automatically named **StoreApp.Tests**. You can keep this name.

After creating the application, you will see it contains two projects.

Add unit test project to an existing application

If you did not create the unit test project when you created your application, you can add one at any time. For example, suppose you already have an application named StoreApp, and you want to add unit tests. To add a unit test project, right-click your solution and select **Add** and **New Project**.

Select **Test** in the left pane, and select **Unit Test Project** for the project type. Name the project **StoreApp.Tests**.

You will see the unit test project in your solution.

In the unit test project, add a project reference to the original project.

Set up the Web API 2 application

In your StoreApp project, add a class file to the **Models** folder named **Product.cs**. Replace the contents of the file with the following code.

```
using System;

namespace StoreApp.Models
{
    public class Product
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public decimal Price { get; set; }
    }
}
```

Build the solution.

Right-click the Controllers folder and select **Add** and **New Scaffolded Item**. Select **Web API 2 Controller - Empty**.

Set the controller name to **SimpleProductController**, and click **Add**.

Replace the existing code with the following code. To simplify this example, the data is stored in a list rather than a database. The list defined in this class represents the production data. Notice that the controller includes a constructor that takes as a parameter a list of Product objects. This constructor enables you to pass test data when unit testing. The controller also includes two **async** methods to illustrate unit testing asynchronous methods. These async methods were implemented by calling **Task.FromResult** to minimize extraneous code, but normally the methods would include resource-intensive operations.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using System.Web.Http;
using StoreApp.Models;

namespace StoreApp.Controllers
{
    public class SimpleProductController : ApiController
    {
        List<Product> products = new List<Product>();

        public SimpleProductController() { }

        public SimpleProductController(List<Product> products)
        {
            this.products = products;
        }

        public IEnumerable<Product> GetAllProducts()
        {
            return products;
        }

        public async Task<IEnumerable<Product>> GetAllProductsAsync()
        {
            return await Task.FromResult(GetAllProducts());
        }

        public IHttpActionResult GetProduct(int id)
        {
            var product = products.FirstOrDefault((p) => p.Id == id);
            if (product == null)
            {
                return NotFound();
            }
            return Ok(product);
        }

        public async Task<IHttpActionResult> GetProductAsync(int id)
        {
            return await Task.FromResult(GetProduct(id));
        }
    }
}
```

The GetProduct method returns an instance of the **IHttpActionResult** interface. IHttpActionResult is one of the new features in Web API 2, and it simplifies unit test development. Classes that implement the IHttpActionResult interface are found in the System.Web.Http.Results namespace. These classes represent possible responses from an action request, and they correspond to HTTP status codes.

Build the solution.

You are now ready to set up the test project.

Install NuGet packages in test project

When you use the Empty template to create an application, the unit test project (StoreApp.Tests) does not include any installed NuGet packages. Other templates, such as the Web API template, include some NuGet packages in the unit test project. For this tutorial, you must include the Microsoft ASP.NET Web API 2 Core package to the test project.

Right-click the StoreApp.Tests project and select **Manage NuGet Packages**. You must select the StoreApp.Tests project to add the packages to that project.

Find and install Microsoft ASP.NET Web API 2 Core package.

Close the Manage NuGet Packages window.

Create tests

By default, your test project includes an empty test file named UnitTest1.cs. This file shows the attributes you use to create test methods. For your unit tests, you can either use this file or create your own file.

For this tutorial, you will create your own test class. You can delete the UnitTest1.cs file. Add a class named **TestSimpleProductController.cs**, and replace the code with the following code.

```
using System;
using System.Collections.Generic;
using System.Threading.Tasks;
```

```
using System.Web.Http.Results;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using StoreApp.Controllers;
using StoreApp.Models;

namespace StoreApp.Tests
{
    [TestClass]
    public class TestSimpleProductController
    {
        [TestMethod]
        public void GetAllProducts_ShouldReturnAllProducts()
        {
            var testProducts = GetTestProducts();
            var controller = new SimpleProductController(testProducts);

            var result = controller.GetAllProducts() as List<Product>;
            Assert.AreEqual(testProducts.Count, result.Count);
        }

        [TestMethod]
        public async Task GetAllProductsAsync_ShouldReturnAllProducts()
        {
            var testProducts = GetTestProducts();
            var controller = new SimpleProductController(testProducts);

            var result = await controller.GetAllProductsAsync() as List<Product>;
            Assert.AreEqual(testProducts.Count, result.Count);
        }

        [TestMethod]
        public void GetProduct_ShouldReturnCorrectProduct()
        {
            var testProducts = GetTestProducts();
            var controller = new SimpleProductController(testProducts);

            var result = controller.GetProduct(4) as OkNegotiatedContentResult<Product>;
            Assert.IsNotNull(result);
            Assert.AreEqual(testProducts[3].Name, result.Content.Name);
        }

        [TestMethod]
        public async Task GetProductAsync_ShouldReturnCorrectProduct()
        {
            var testProducts = GetTestProducts();
            var controller = new SimpleProductController(testProducts);

            var result = await controller.GetProductAsync(4) as OkNegotiatedContentResult<Product>;
            Assert.IsNotNull(result);
            Assert.AreEqual(testProducts[3].Name, result.Content.Name);
        }

        [TestMethod]
        public void GetProduct_ShouldNotFindProduct()
        {
            var controller = new SimpleProductController(GetTestProducts());

            var result = controller.GetProduct(999);
            Assert.IsInstanceOfType(result, typeof(NotFoundResult));
        }

        private List<Product> GetTestProducts()
        {
            var testProducts = new List<Product>();
            testProducts.Add(new Product { Id = 1, Name = "Demo1", Price = 1 });
            testProducts.Add(new Product { Id = 2, Name = "Demo2", Price = 3.75M });
            testProducts.Add(new Product { Id = 3, Name = "Demo3", Price = 16.99M });
            testProducts.Add(new Product { Id = 4, Name = "Demo4", Price = 11.00M });
```

```
            return testProducts;
        }
    }
}
```

Run tests

You are now ready to run the tests. All of the method that are marked with the **TestMethod** attribute will be tested. From the **Test** menu item, run the tests.

Open the **Test Explorer** window, and notice the results of the tests.

Summary

You have completed this tutorial. The data in this tutorial was intentionally simplified to focus on unit testing conditions. For unit testing more advanced data scenarios, see Mocking Entity Framework when Unit Testing ASP.NET Web API 2.

Unit Testing Controllers in ASP.NET Web API 2

9/16/2020 • 6 minutes to read • Edit Online

by Mike Wasson

This topic describes some specific techniques for unit testing controllers in Web API 2. Before reading this topic, you might want to read the tutorial Unit Testing ASP.NET Web API 2, which shows how to add a unit-test project to your solution.

Software versions used in the tutorial

- Visual Studio 2017
- Web API 2
- Moq 4.5.30

> **NOTE**
>
> I used Moq, but the same idea applies to any mocking framework. Moq 4.5.30 (and later) supports Visual Studio 2017, Roslyn and .NET 4.5 and later versions.

A common pattern in unit tests is "arrange-act-assert":

- Arrange: Set up any prerequisites for the test to run.
- Act: Perform the test.
- Assert: Verify that the test succeeded.

In the arrange step, you will often use mock or stub objects. That minimizes the number of dependencies, so the test is focused on testing one thing.

Here are some things that you should unit test in your Web API controllers:

- The action returns the correct type of response.
- Invalid parameters return the correct error response.
- The action calls the correct method on the repository or service layer.
- If the response includes a domain model, verify the model type.

These are some of the general things to test, but the specifics depend on your controller implementation. In particular, it makes a big difference whether your controller actions return **HttpResponseMessage** or **IHttpActionResult**. For more information about these result types, see Action Results in Web Api 2.

Testing Actions that Return HttpResponseMessage

Here is an example of a controller whose actions return **HttpResponseMessage**.

```
public class ProductsController : ApiController
{
    IProductRepository _repository;

    public ProductsController(IProductRepository repository)
    {
        _repository = repository;
    }

    public HttpResponseMessage Get(int id)
    {
        Product product = _repository.GetById(id);
        if (product == null)
        {
            return Request.CreateResponse(HttpStatusCode.NotFound);
        }
        return Request.CreateResponse(product);
    }

    public HttpResponseMessage Post(Product product)
    {
        _repository.Add(product);

        var response = Request.CreateResponse(HttpStatusCode.Created, product);
        string uri = Url.Link("DefaultApi", new { id = product.Id });
        response.Headers.Location = new Uri(uri);

        return response;
    }
}
```

Notice the controller uses dependency injection to inject an `IProductRepository`. That makes the controller more testable, because you can inject a mock repository. The following unit test verifies that the `Get` method writes a `Product` to the response body. Assume that `repository` is a mock `IProductRepository`.

```
[TestMethod]
public void GetReturnsProduct()
{
    // Arrange
    var controller = new ProductsController(repository);
    controller.Request = new HttpRequestMessage();
    controller.Configuration = new HttpConfiguration();

    // Act
    var response = controller.Get(10);

    // Assert
    Product product;
    Assert.IsTrue(response.TryGetContentValue<Product>(out product));
    Assert.AreEqual(10, product.Id);
}
```

It's important to set **Request** and **Configuration** on the controller. Otherwise, the test will fail with an **ArgumentNullException** or **InvalidOperationException**.

Testing Link Generation

The `Post` method calls **UrlHelper.Link** to create links in the response. This requires a little more setup in the unit test:

```
[TestMethod]
public void PostSetsLocationHeader()
{
    // Arrange
    ProductsController controller = new ProductsController(repository);

    controller.Request = new HttpRequestMessage {
        RequestUri = new Uri("http://localhost/api/products")
    };
    controller.Configuration = new HttpConfiguration();
    controller.Configuration.Routes.MapHttpRoute(
        name: "DefaultApi",
        routeTemplate: "api/{controller}/{id}",
        defaults: new { id = RouteParameter.Optional });

    controller.RequestContext.RouteData = new HttpRouteData(
        route: new HttpRoute(),
        values: new HttpRouteValueDictionary { { "controller", "products" } });

    // Act
    Product product = new Product() { Id = 42, Name = "Product1" };
    var response = controller.Post(product);

    // Assert
    Assert.AreEqual("http://localhost/api/products/42", response.Headers.Location.AbsoluteUri);
}
```

The **UrlHelper** class needs the request URL and route data, so the test has to set values for these. Another option is mock or stub **UrlHelper**. With this approach, you replace the default value of ApiController.Url with a mock or stub version that returns a fixed value.

Let's rewrite the test using the Moq framework. Install the `Moq` NuGet package in the test project.

```
[TestMethod]
public void PostSetsLocationHeader_MockVersion()
{
    // This version uses a mock UrlHelper.

    // Arrange
    ProductsController controller = new ProductsController(repository);
    controller.Request = new HttpRequestMessage();
    controller.Configuration = new HttpConfiguration();

    string locationUrl = "http://location/";

    // Create the mock and set up the Link method, which is used to create the Location header.
    // The mock version returns a fixed string.
    var mockUrlHelper = new Mock<UrlHelper>();
    mockUrlHelper.Setup(x => x.Link(It.IsAny<string>(), It.IsAny<object>())).Returns(locationUrl);
    controller.Url = mockUrlHelper.Object;

    // Act
    Product product = new Product() { Id = 42 };
    var response = controller.Post(product);

    // Assert
    Assert.AreEqual(locationUrl, response.Headers.Location.AbsoluteUri);
}
```

In this version, you don't need to set up any route data, because the mock **UrlHelper** returns a constant string.

Testing Actions that Return IHttpActionResult

In Web API 2, a controller action can return **IHttpActionResult**, which is analogous to **ActionResult** in ASP.NET MVC. The **IHttpActionResult** interface defines a command pattern for creating HTTP responses. Instead of creating the response directly, the controller returns an **IHttpActionResult**. Later, the pipeline invokes the **IHttpActionResult** to create the response. This approach makes it easier to write unit tests, because you can skip a lot of the setup that is needed for **HttpResponseMessage**.

Here is an example controller whose actions return **IHttpActionResult**.

```
public class Products2Controller : ApiController
{
    IProductRepository _repository;

    public Products2Controller(IProductRepository repository)
    {
        _repository = repository;
    }

    public IHttpActionResult Get(int id)
    {
        Product product = _repository.GetById(id);
        if (product == null)
        {
            return NotFound();
        }
        return Ok(product);
    }

    public IHttpActionResult Post(Product product)
    {
        _repository.Add(product);
        return CreatedAtRoute("DefaultApi", new { id = product.Id }, product);
    }

    public IHttpActionResult Delete(int id)
    {
        _repository.Delete(id);
        return Ok();
    }

    public IHttpActionResult Put(Product product)
    {
        // Do some work (not shown).
        return Content(HttpStatusCode.Accepted, product);
    }
}
```

This example shows some common patterns using **IHttpActionResult**. Let's see how to unit test them.

Action returns 200 (OK) with a response body

The `Get` method calls `Ok(product)` if the product is found. In the unit test, make sure the return type is **OkNegotiatedContentResult** and the returned product has the right ID.

```
[TestMethod]
public void GetReturnsProductWithSameId()
{
    // Arrange
    var mockRepository = new Mock<IProductRepository>();
    mockRepository.Setup(x => x.GetById(42))
        .Returns(new Product { Id = 42 });

    var controller = new Products2Controller(mockRepository.Object);

    // Act
    IHttpActionResult actionResult = controller.Get(42);
    var contentResult = actionResult as OkNegotiatedContentResult<Product>;

    // Assert
    Assert.IsNotNull(contentResult);
    Assert.IsNotNull(contentResult.Content);
    Assert.AreEqual(42, contentResult.Content.Id);
}
```

Notice that the unit test doesn't execute the action result. You can assume the action result creates the HTTP response correctly. (That's why the Web API framework has its own unit tests!)

Action returns 404 (Not Found)

The `Get` method calls `NotFound()` if the product is not found. For this case, the unit test just checks if the return type is **NotFoundResult**.

```
[TestMethod]
public void GetReturnsNotFound()
{
    // Arrange
    var mockRepository = new Mock<IProductRepository>();
    var controller = new Products2Controller(mockRepository.Object);

    // Act
    IHttpActionResult actionResult = controller.Get(10);

    // Assert
    Assert.IsInstanceOfType(actionResult, typeof(NotFoundResult));
}
```

Action returns 200 (OK) with no response body

The `Delete` method calls `Ok()` to return an empty HTTP 200 response. Like the previous example, the unit test checks the return type, in this case **OkResult**.

```
[TestMethod]
public void DeleteReturnsOk()
{
    // Arrange
    var mockRepository = new Mock<IProductRepository>();
    var controller = new Products2Controller(mockRepository.Object);

    // Act
    IHttpActionResult actionResult = controller.Delete(10);

    // Assert
    Assert.IsInstanceOfType(actionResult, typeof(OkResult));
}
```

Action returns 201 (Created) with a Location header

The `Post` method calls `CreatedAtRoute` to return an HTTP 201 response with a URI in the Location header. In the unit test, verify that the action sets the correct routing values.

```
[TestMethod]
public void PostMethodSetsLocationHeader()
{
    // Arrange
    var mockRepository = new Mock<IProductRepository>();
    var controller = new Products2Controller(mockRepository.Object);

    // Act
    IHttpActionResult actionResult = controller.Post(new Product { Id = 10, Name = "Product1" });
    var createdResult = actionResult as CreatedAtRouteNegotiatedContentResult<Product>;

    // Assert
    Assert.IsNotNull(createdResult);
    Assert.AreEqual("DefaultApi", createdResult.RouteName);
    Assert.AreEqual(10, createdResult.RouteValues["id"]);
}
```

Action returns another 2xx with a response body

The `Put` method calls `Content` to return an HTTP 202 (Accepted) response with a response body. This case is similar to returning 200 (OK), but the unit test should also check the status code.

```
[TestMethod]
public void PutReturnsContentResult()
{
    // Arrange
    var mockRepository = new Mock<IProductRepository>();
    var controller = new Products2Controller(mockRepository.Object);

    // Act
    IHttpActionResult actionResult = controller.Put(new Product { Id = 10, Name = "Product" });
    var contentResult = actionResult as NegotiatedContentResult<Product>;

    // Assert
    Assert.IsNotNull(contentResult);
    Assert.AreEqual(HttpStatusCode.Accepted, contentResult.StatusCode);
    Assert.IsNotNull(contentResult.Content);
    Assert.AreEqual(10, contentResult.Content.Id);
}
```

Mocking Entity Framework when Unit Testing ASP.NET Web API 2

2/20/2020 • 8 minutes to read • Edit Online

by Tom FitzMacken

Download Completed Project

This guidance and application demonstrate how to create unit tests for your Web API 2 application that uses the Entity Framework. It shows how to modify the scaffolded controller to enable passing a context object for testing, and how to create test objects that work with Entity Framework.

For an introduction to unit testing with ASP.NET Web API, see Unit Testing with ASP.NET Web API 2.

This tutorial assumes you are familiar with the basic concepts of ASP.NET Web API. For an introductory tutorial, see Getting Started with ASP.NET Web API 2.

Software versions used in the tutorial

- Visual Studio 2017
- Web API 2

In this topic

This topic contains the following sections:

- Prerequisites
- Download code
- Create application with unit test project
- Create the model class
- Add the controller
- Add dependency injection
- Install NuGet packages in test project
- Create test context
- Create tests
- Run tests

If you have already completed the steps in Unit Testing with ASP.NET Web API 2, you can skip to the section Add the controller.

Prerequisites

Visual Studio 2017 Community, Professional or Enterprise edition

Download code

Download the completed project. The downloadable project includes unit test code for this topic and for the Unit Testing ASP.NET Web API 2 topic.

Create application with unit test project

You can either create a unit test project when creating your application or add a unit test project to an existing application. This tutorial shows creating a unit test project when creating the application.

Create a new ASP.NET Web Application named **StoreApp**.

In the New ASP.NET Project windows, select the **Empty** template and add folders and core references for Web API. Select the **Add unit tests** option. The unit test project is automatically named **StoreApp.Tests**. You can keep this name.

After creating the application, you will see it contains two projects - **StoreApp** and **StoreApp.Tests**.

Create the model class

In your StoreApp project, add a class file to the **Models** folder named **Product.cs**. Replace the contents of the file with the following code.

```
using System;

namespace StoreApp.Models
{
    public class Product
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public decimal Price { get; set; }
    }
}
```

Build the solution.

Add the controller

Right-click the Controllers folder and select **Add** and **New Scaffolded Item**. Select Web API 2 Controller with

actions, using Entity Framework.

Set the following values:

- Controller name: **ProductController**
- Model class: **Product**
- Data context class: [Select **New data context** button which fills in the values seen below]

Click **Add** to create the controller with automatically-generated code. The code includes methods for creating, retrieving, updating and deleting instances of the Product class. The following code shows the method for add a Product. Notice that the method returns an instance of **IHttpActionResult**.

```
// POST api/Product
[ResponseType(typeof(Product))]
public IHttpActionResult PostProduct(Product product)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    db.Products.Add(product);
    db.SaveChanges();

    return CreatedAtRoute("DefaultApi", new { id = product.Id }, product);
}
```

IHttpActionResult is one of the new features in Web API 2, and it simplifies unit test development.

In the next section, you will customize the generated code to facilitate passing test objects to the controller.

Add dependency injection

Currently, the ProductController class is hard-coded to use an instance of the StoreAppContext class. You will use

a pattern called dependency injection to modify your application and remove that hard-coded dependency. By breaking this dependency, you can pass in a mock object when testing.

Right-click the **Models** folder, and add a new interface named **IStoreAppContext**.

Replace the code with the following code.

```
using System;
using System.Data.Entity;

namespace StoreApp.Models
{
    public interface IStoreAppContext : IDisposable
    {
        DbSet<Product> Products { get; }
        int SaveChanges();
        void MarkAsModified(Product item);
    }
}
```

Open the StoreAppContext.cs file and make the following highlighted changes. The important changes to note are:

- StoreAppContext class implements IStoreAppContext interface
- MarkAsModified method is implemented

```
using System;
using System.Data.Entity;

namespace StoreApp.Models
{
    public class StoreAppContext : DbContext, IStoreAppContext
    {
        public StoreAppContext() : base("name=StoreAppContext")
        {
        }

        public DbSet<Product> Products { get; set; }

        public void MarkAsModified(Product item)
        {
            Entry(item).State = EntityState.Modified;
        }
    }
}
```

Open the ProductController.cs file. Change the existing code to match the highlighted code. These changes break the dependency on StoreAppContext and enable other classes to pass in a different object for the context class. This change will enable you to pass in a test context during unit tests.

```
public class ProductController : ApiController
{
    // modify the type of the db field
    private IStoreAppContext db = new StoreAppContext();

    // add these constructors
    public ProductController() { }

    public ProductController(IStoreAppContext context)
    {
        db = context;
    }
    // rest of class not shown
}
```

There is one more change you must make in ProductController. In the **PutProduct** method, replace the line that sets the entity state to modified with a call to the MarkAsModified method.

```
// PUT api/Product/5
public IHttpActionResult PutProduct(int id, Product product)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    if (id != product.Id)
    {
        return BadRequest();
    }

    //db.Entry(product).State = EntityState.Modified;
    db.MarkAsModified(product);

    // rest of method not shown
}
```

Build the solution.

You are now ready to set up the test project.

Install NuGet packages in test project

When you use the Empty template to create an application, the unit test project (StoreApp.Tests) does not include any installed NuGet packages. Other templates, such as the Web API template, include some NuGet packages in the unit test project. For this tutorial, you must include the Entity Framework package and the Microsoft ASP.NET Web API 2 Core package to the test project.

Right-click the StoreApp.Tests project and select **Manage NuGet Packages**. You must select the StoreApp.Tests project to add the packages to that project.

From the Online packages, find and install the EntityFramework package (version 6.0 or later). If it appears that the EntityFramework package is already installed, you may have selected the StoreApp project instead of the StoreApp.Tests project.

Find and install Microsoft ASP.NET Web API 2 Core package.

Close the Manage NuGet Packages window.

Create test context

Add a class named **TestDbSet** to the test project. This class serves as the base class for your test data set. Replace the code with the following code.

```
using System;
using System.Collections.Generic;
using System.Collections.ObjectModel;
using System.Data.Entity;
using System.Linq;

namespace StoreApp.Tests
{
    public class TestDbSet<T> : DbSet<T>, IQueryable, IEnumerable<T>
        where T : class
    {
        ObservableCollection<T> _data;
        IQueryable _query;

        public TestDbSet()
        {
            _data = new ObservableCollection<T>();
            _query = _data.AsQueryable();
        }

        public override T Add(T item)
        {
            _data.Add(item);
            return item;
        }

        public override T Remove(T item)
        {
            _data.Remove(item);
            return item;
        }

        public override T Attach(T item)
        {
            _data.Add(item);
            return item;
```

```
        }

        public override T Create()
        {
            return Activator.CreateInstance<T>();
        }

        public override TDerivedEntity Create<TDerivedEntity>()
        {
            return Activator.CreateInstance<TDerivedEntity>();
        }

        public override ObservableCollection<T> Local
        {
            get { return new ObservableCollection<T>(_data); }
        }

        Type IQueryable.ElementType
        {
            get { return _query.ElementType; }
        }

        System.Linq.Expressions.Expression IQueryable.Expression
        {
            get { return _query.Expression; }
        }

        IQueryProvider IQueryable.Provider
        {
            get { return _query.Provider; }
        }

        System.Collections.IEnumerator System.Collections.IEnumerable.GetEnumerator()
        {
            return _data.GetEnumerator();
        }

        IEnumerator<T> IEnumerable<T>.GetEnumerator()
        {
            return _data.GetEnumerator();
        }
    }
}
```

Add a class named **TestProductDbSet** to the test project which contains the following code.

```
using System;
using System.Linq;
using StoreApp.Models;

namespace StoreApp.Tests
{
    class TestProductDbSet : TestDbSet<Product>
    {
        public override Product Find(params object[] keyValues)
        {
            return this.SingleOrDefault(product => product.Id == (int)keyValues.Single());
        }
    }
}
```

Add a class named **TestStoreAppContext** and replace the existing code with the following code.

```
using System;
using System.Data.Entity;
using StoreApp.Models;

namespace StoreApp.Tests
{
    public class TestStoreAppContext : IStoreAppContext
    {
        public TestStoreAppContext()
        {
            this.Products = new TestProductDbSet();
        }

        public DbSet<Product> Products { get; set; }

        public int SaveChanges()
        {
            return 0;
        }

        public void MarkAsModified(Product item) { }
        public void Dispose() { }
    }
}
```

Create tests

By default, your test project includes an empty test file named **UnitTest1.cs**. This file shows the attributes you use to create test methods. For this tutorial, you can delete this file because you will add a new test class.

Add a class named **TestProductController** to the test project. Replace the code with the following code.

```
using System;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using System.Web.Http.Results;
using System.Net;
using StoreApp.Models;
using StoreApp.Controllers;

namespace StoreApp.Tests
{
    [TestClass]
    public class TestProductController
    {
        [TestMethod]
        public void PostProduct_ShouldReturnSameProduct()
        {
            var controller = new ProductController(new TestStoreAppContext());

            var item = GetDemoProduct();

            var result =
                controller.PostProduct(item) as CreatedAtRouteNegotiatedContentResult<Product>;

            Assert.IsNotNull(result);
            Assert.AreEqual(result.RouteName, "DefaultApi");
            Assert.AreEqual(result.RouteValues["id"], result.Content.Id);
            Assert.AreEqual(result.Content.Name, item.Name);
        }

        [TestMethod]
        public void PutProduct_ShouldReturnStatusCode()
        {
            var controller = new ProductController(new TestStoreAppContext());
```

```
            var item = GetDemoProduct();

            var result = controller.PutProduct(item.Id, item) as StatusCodeResult;
            Assert.IsNotNull(result);
            Assert.IsInstanceOfType(result, typeof(StatusCodeResult));
            Assert.AreEqual(HttpStatusCode.NoContent, result.StatusCode);
        }

        [TestMethod]
        public void PutProduct_ShouldFail_WhenDifferentID()
        {
            var controller = new ProductController(new TestStoreAppContext());

            var badresult = controller.PutProduct(999, GetDemoProduct());
            Assert.IsInstanceOfType(badresult, typeof(BadRequestResult));
        }

        [TestMethod]
        public void GetProduct_ShouldReturnProductWithSameID()
        {
            var context = new TestStoreAppContext();
            context.Products.Add(GetDemoProduct());

            var controller = new ProductController(context);
            var result = controller.GetProduct(3) as OkNegotiatedContentResult<Product>;

            Assert.IsNotNull(result);
            Assert.AreEqual(3, result.Content.Id);
        }

        [TestMethod]
        public void GetProducts_ShouldReturnAllProducts()
        {
            var context = new TestStoreAppContext();
            context.Products.Add(new Product { Id = 1, Name = "Demo1", Price = 20 });
            context.Products.Add(new Product { Id = 2, Name = "Demo2", Price = 30 });
            context.Products.Add(new Product { Id = 3, Name = "Demo3", Price = 40 });

            var controller = new ProductController(context);
            var result = controller.GetProducts() as TestProductDbSet;

            Assert.IsNotNull(result);
            Assert.AreEqual(3, result.Local.Count);
        }

        [TestMethod]
        public void DeleteProduct_ShouldReturnOK()
        {
            var context = new TestStoreAppContext();
            var item = GetDemoProduct();
            context.Products.Add(item);

            var controller = new ProductController(context);
            var result = controller.DeleteProduct(3) as OkNegotiatedContentResult<Product>;

            Assert.IsNotNull(result);
            Assert.AreEqual(item.Id, result.Content.Id);
        }

        Product GetDemoProduct()
        {
            return new Product() { Id = 3, Name = "Demo name", Price = 5 };
        }
    }
}
```

Run tests

You are now ready to run the tests. All of the method that are marked with the **TestMethod** attribute will be tested. From the **Test** menu item, run the tests.

Open the **Test Explorer** window, and notice the results of the tests.

Troubleshoot Web API2 apps that work in Visual Studio and fail on a production IIS server

2/20/2020 • 8 minutes to read • Edit Online

This doc explains how to troubleshoot Web API2 apps that are deployed to a production IIS server. It addresses common HTTP 405 and 501 errors.

Software used in this tutorial

- Internet Information Services (IIS) (version 7 or later)
- Web API

Web API apps typically use several HTTP verbs: GET, POST, PUT, DELETE, and sometimes PATCH. That being said, developers may run into situations where those verbs are implemented by another IIS module on their production IIS server, which leads to a situation where a Web API controller that works correctly in Visual Studio or on a development server will return an HTTP 405 error when it is deployed to a production IIS server.

What causes HTTP 405 errors

The first step toward learning how to troubleshoot HTTP 405 errors is to understand what an HTTP 405 error actually means. The primary governing document for HTTP is RFC 2616, which defines the HTTP 405 status code as ***Method Not Allowed***, and further describes this status code as a situation where "the method specified in the Request-Line is not allowed for the resource identified by the Request-URI." In other words, the HTTP verb is not allowed for the specific URL that an HTTP client has requested.

As a brief review, here are several of the most-used HTTP methods as defined in RFC 2616, RFC 4918, and RFC 5789:

HTTP METHOD	DESCRIPTION
GET	This method is used to retrieve data from a URI, and it probably the most-used HTTP method.
HEAD	This method is much like the GET method, except that it doesn't actually retrieve the data from the request URI - it simply retrieves the HTTP status.
POST	This method is typically used to send new data to the URI; POST is often used to submit form data.
PUT	This method is typically used to send raw data to the URI; PUT is often used to submit JSON or XML data to Web API applications.
DELETE	This method is used to remove data from a URI.
OPTIONS	This method is typically used to retrieve the list of HTTP methods that are supported for a URI.

HTTP METHOD	DESCRIPTION
COPY MOVE	These two methods are used with WebDAV, and their purpose is self-explanatory.
MKCOL	This method is used with WebDAV, and it is used to create a collection (e.g. a directory) at the specified URI.
PROPFIND PROPPATCH	These two methods are used with WebDAV, and they are used to query or set properties for a URI.
LOCK UNLOCK	These two methods are used with WebDAV, and they are used to lock/unlock the resource identified by the request URI when authoring.
PATCH	This method is used to modify an existing HTTP resource.

When one of these HTTP methods is configured for use on the server, the server will respond with the HTTP status and other data that is appropriate for the request. (For example, a GET method might receive an HTTP 200 ***OK*** response, and a PUT method might receive an HTTP 201 ***Created*** response.)

If the HTTP method is not configured for use on the server, the server will respond with an HTTP 501 ***Not Implemented*** error.

However, when an HTTP method is configured for use on the server, but it has been disabled for a given URI, the server will respond with an HTTP 405 ***Method Not Allowed*** error.

Example HTTP 405 error

The following example HTTP request and response illustrate a situation where an HTTP client is attempting to PUT value to a Web API app on a web server, and the server returns an HTTP error which states that the PUT method is not allowed:

HTTP Request:

```
PUT /api/values/1 HTTP/1.1
Content-type: application/json
Host: localhost
Accept: */*
Content-Length: 12

"Some Value"
```

HTTP Response:

```
HTTP/1.1 405 Method Not Allowed
Cache-Control: no-cache
Pragma: no-cache
Content-Type: application/json; charset=utf-8
Expires: -1
Server: Microsoft-IIS/8.0
X-Powered-By: ASP.NET
Date: Wed, 15 May 2013 02:38:57 GMT
Content-Length: 72

{"Message":"The requested resource does not support http method 'PUT'."}
```

In this example, the HTTP client sent a valid JSON request to the URL for a Web API application on a web server, but the server returned an HTTP 405 error message which indicates that the PUT method was not allowed for the URL. In contrast, if the request URI did not match a route for the Web API application, the server would return an HTTP 404 ***Not Found*** error.

Resolve HTTP 405 errors

There are several reasons why a specific HTTP verb may not be allowed, but there is one primary scenario that is the leading cause of this error in IIS: multiple handlers are defined for the same verb/method, and one of the handlers is blocking the expected handler from processing the request. By way of explanation, IIS processes handlers from first to last based on the order handler entries in the *applicationHost.config* and *web.config* files, where the first matching combination of path, verb, resource, etc., will be used to handle the request.

The following example is an excerpt from an *applicationHost.config* file for an IIS server that was returning an HTTP 405 error when using the PUT method to submit data to a Web API application. In this excerpt, several HTTP handlers are defined, and each handler has a different set of HTTP methods for which it is configured - the last entry in the list is the static content handler, which is the default handler that is used after the other handlers have had a chance to examine the request:

```
<handlers accessPolicy="Read, Script">
   <add name="WebDAV"
      path="*"
      verb="PROPFIND,PROPPATCH,MKCOL,PUT,COPY,DELETE,MOVE,LOCK,UNLOCK"
      modules="WebDAVModule"
      resourceType="Unspecified"
      requireAccess="None" />
   <add name="ISAPI-dll"
      path="*.dll"
      verb="*"
      modules="IsapiModule"
      resourceType="File"
      requireAccess="Execute"
      allowPathInfo="true" />
   <add name="ExtensionlessUrlHandler-ISAPI-4.0_64bit"
      path="*."
      verb="GET,HEAD,POST,DEBUG"
      modules="IsapiModule"
      scriptProcessor="%windir%\Microsoft.NET\Framework64\v4.0.30319\aspnet_isapi.dll"
      preCondition="classicMode,runtimeVersionv4.0,bitness64"
      responseBufferLimit="0" />

   <!-- Additional handlers will be defined here. -->

   <add name="StaticFile"
      path="*"
      verb="*"
      modules="StaticFileModule,DefaultDocumentModule,DirectoryListingModule"
      resourceType="Either"
      requireAccess="Read" />
</handlers>
```

In the preceding example, the WebDAV handler and the Extension-less URL Handler for ASP.NET (which is used for Web API) are clearly defined for separate lists of HTTP methods. Note that the ISAPI DLL handler is configured for all HTTP methods, although this configuration will not necessarily cause an error. However, configuration settings like this need to be considered when troubleshooting HTTP 405 errors.

In the preceding example, the ISAPI DLL handler was not the problem; in fact, the problem was not defined in the *applicationHost.config* file for the IIS server - the problem was caused by an entry that was made in the *web.config* file when the Web API application was created in Visual Studio. The following excerpt from the application's *web.config* file shows the location of the problem:

```
<handlers accessPolicy="Read, Script">
   <remove name="ExtensionlessUrlHandler-ISAPI-4.0_64bit" />
   <add name="ExtensionlessUrlHandler-ISAPI-4.0_64bit"
      path="*."
      verb="GET,HEAD,POST,DEBUG,PUT,DELETE,PATCH,OPTIONS"
      modules="IsapiModule"
      scriptProcessor="%windir%\Microsoft.NET\Framework64\v4.0.30319\aspnet_isapi.dll"
      preCondition="classicMode,runtimeVersionv4.0,bitness64"
      responseBufferLimit="0" />
</handlers>
```

In this excerpt, the Extension-less URL Handler for ASP.NET is redefined to include additional HTTP methods that will be used with the Web API application. However, since a similar set of HTTP methods is defined for the WebDAV handler, a conflict occurs. In this specific case, the WebDAV handler is defined and loaded by IIS, even though WebDAV is disabled for the website that includes the Web API application. During the processing of an HTTP PUT request, IIS calls the WebDAV module since it is defined for the PUT verb. When the WebDAV module is called, it checks its configuration and sees that it is disabled, so it will return an HTTP 405 ***Method Not Allowed*** error for any request that resembles a WebDAV request. To resolve this issue, you should remove WebDAV from the list of HTTP modules for the website where your Web API application is defined. The following example shows what that might look like:

```
<handlers accessPolicy="Read, Script">
   <remove name="WebDAV" />
   <remove name="ExtensionlessUrlHandler-ISAPI-4.0_64bit" />
   <add name="ExtensionlessUrlHandler-ISAPI-4.0_64bit"
      path="*."
      verb="GET,HEAD,POST,DEBUG,PUT,DELETE,PATCH,OPTIONS"
      modules="IsapiModule"
      scriptProcessor="%windir%\Microsoft.NET\Framework64\v4.0.30319\aspnet_isapi.dll"
      preCondition="classicMode,runtimeVersionv4.0,bitness64"
      responseBufferLimit="0" />
</handlers>
```

This scenario is often encountered after an application is published from a development environment to an IIS production environment, and this occurs because the list of handlers/modules is different between your development and production environments. For example, if you are using Visual Studio 2012 or later to develop a Web API application, IIS Express is the default web server for testing. This development web server is a scaled-down version of the full IIS functionality that ships in a server product, and this development web server contains a few changes that were added for development scenarios. For example, the WebDAV module is often installed on a production web server that is running the full version of IIS, although it may not be in use. The development version of IIS, (IIS Express), installs the WebDAV module, but the entries for the WebDAV module are intentionally commented out, so the WebDAV module is never loaded on IIS Express unless you specifically alter your IIS Express configuration settings to add WebDAV functionality to your IIS Express installation. As a result, your web application may work correctly on your development computer, but you may encounter HTTP 405 errors when you publish your Web API application to your production IIS web server.

HTTP 501 errors

- Indicates the specific functionality has not been implemented on the server.
- Typically means that there is no handler defined in your IIS settings which matches the HTTP request:
  - Probably indicates that something was not installed correctly on IIS or
  - Something has modified your IIS settings so that there are no handlers defined that support the specific HTTP method.

To resolve that issue, you would need to reinstall any application that is attempting to use an HTTP method for

which it has no corresponding module or handler definitions.

Summary

HTTP 405 errors are caused when an HTTP method is not allowed by a web server for a requested URL. This condition is often seen when a particular handler has been defined for a specific verb, and that handler is overriding the handler that you expect to process the request.

Security, Authentication, and Authorization in ASP.NET Web API

2/20/2020 • 2 minutes to read • Edit Online

Security issues for Web API.

- Authentication and Authorization in Web API
- Secure a Web API with Individual Accounts in Web API 2.2
- External Authentication Services with Web API (C#)
- Preventing Cross-Site Request Forgery (CSRF) Attacks in Web API
- Enabling Cross-Origin Requests in Web API 2
- Authentication Filters in Web API 2

- Forms Authentication in Web API
- Integrated Windows Authentication
- Working with SSL

Authentication and Authorization in ASP.NET Web API

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

You've created a web API, but now you want to control access to it. In this series of articles, we'll look at some options for securing a web API from unauthorized users. This series will cover both authentication and authorization.

- *Authentication* is knowing the identity of the user. For example, Alice logs in with her username and password, and the server uses the password to authenticate Alice.
- *Authorization* is deciding whether a user is allowed to perform an action. For example, Alice has permission to get a resource but not create a resource.

The first article in the series gives a general overview of authentication and authorization in ASP.NET Web API. Other topics describe common authentication scenarios for Web API.

> **NOTE**

> Thanks to the people who reviewed this series and provided valuable feedback: Rick Anderson, Levi Broderick, Barry Dorrans, Tom Dykstra, Hongmei Ge, David Matson, Daniel Roth, Tim Teebken.

Authentication

Web API assumes that authentication happens in the host. For web-hosting, the host is IIS, which uses HTTP modules for authentication. You can configure your project to use any of the authentication modules built in to IIS or ASP.NET, or write your own HTTP module to perform custom authentication.

When the host authenticates the user, it creates a *principal*, which is an IPrincipal object that represents the security context under which code is running. The host attaches the principal to the current thread by setting **Thread.CurrentPrincipal**. The principal contains an associated **Identity** object that contains information about the user. If the user is authenticated, the **Identity.IsAuthenticated** property returns **true**. For anonymous requests, **IsAuthenticated** returns **false**. For more information about principals, see Role-Based Security.

HTTP Message Handlers for Authentication

Instead of using the host for authentication, you can put authentication logic into an HTTP message handler. In that case, the message handler examines the HTTP request and sets the principal.

When should you use message handlers for authentication? Here are some tradeoffs:

- An HTTP module sees all requests that go through the ASP.NET pipeline. A message handler only sees requests that are routed to Web API.
- You can set per-route message handlers, which lets you apply an authentication scheme to a specific route.
- HTTP modules are specific to IIS. Message handlers are host-agnostic, so they can be used with both web-hosting and self-hosting.
- HTTP modules participate in IIS logging, auditing, and so on.
- HTTP modules run earlier in the pipeline. If you handle authentication in a message handler, the principal does not get set until the handler runs. Moreover, the principal reverts back to the previous principal when the response leaves the message handler.

Generally, if you don't need to support self-hosting, an HTTP module is a better option. If you need to support self-hosting, consider a message handler.

Setting the Principal

If your application performs any custom authentication logic, you must set the principal on two places:

- **Thread.CurrentPrincipal**. This property is the standard way to set the thread's principal in .NET.
- **HttpContext.Current.User**. This property is specific to ASP.NET.

The following code shows how to set the principal:

```
private void SetPrincipal(IPrincipal principal)
{
    Thread.CurrentPrincipal = principal;
    if (HttpContext.Current != null)
    {
        HttpContext.Current.User = principal;
    }
}
```

For web-hosting, you must set the principal in both places; otherwise the security context may become inconsistent. For self-hosting, however, **HttpContext.Current** is null. To ensure your code is host-agnostic, therefore, check for null before assigning to **HttpContext.Current**, as shown.

Authorization

Authorization happens later in the pipeline, closer to the controller. That lets you make more granular choices when you grant access to resources.

- *Authorization filters* run before the controller action. If the request is not authorized, the filter returns an error response, and the action is not invoked.
- Within a controller action, you can get the current principal from the **ApiController.User** property. For example, you might filter a list of resources based on the user name, returning only those resources that belong to that user.

Using the [Authorize] Attribute

Web API provides a built-in authorization filter, AuthorizeAttribute. This filter checks whether the user is authenticated. If not, it returns HTTP status code 401 (Unauthorized), without invoking the action.

You can apply the filter globally, at the controller level, or at the level of individual actions.

Globally: To restrict access for every Web API controller, add the **AuthorizeAttribute** filter to the global filter list:

```
public static void Register(HttpConfiguration config)
{
    config.Filters.Add(new AuthorizeAttribute());
}
```

Controller: To restrict access for a specific controller, add the filter as an attribute to the controller:

```
// Require authorization for all actions on the controller.
[Authorize]
public class ValuesController : ApiController
{
    public HttpResponseMessage Get(int id) { ... }
    public HttpResponseMessage Post() { ... }
}
```

Action: To restrict access for specific actions, add the attribute to the action method:

```
public class ValuesController : ApiController
{
    public HttpResponseMessage Get() { ... }

    // Require authorization for a specific action.
    [Authorize]
    public HttpResponseMessage Post() { ... }
}
```

Alternatively, you can restrict the controller and then allow anonymous access to specific actions, by using the `[AllowAnonymous]` attribute. In the following example, the `Post` method is restricted, but the `Get` method allows anonymous access.

```
[Authorize]
public class ValuesController : ApiController
{
    [AllowAnonymous]
    public HttpResponseMessage Get() { ... }

    public HttpResponseMessage Post() { ... }
}
```

In the previous examples, the filter allows any authenticated user to access the restricted methods; only anonymous users are kept out. You can also limit access to specific users or to users in specific roles:

```
// Restrict by user:
[Authorize(Users="Alice,Bob")]
public class ValuesController : ApiController
{
}

// Restrict by role:
[Authorize(Roles="Administrators")]
public class ValuesController : ApiController
{
}
```

> **NOTE**
>
> The **AuthorizeAttribute** filter for Web API controllers is located in the **System.Web.Http** namespace. There is a similar filter for MVC controllers in the **System.Web.Mvc** namespace, which is not compatible with Web API controllers.

Custom Authorization Filters

To write a custom authorization filter, derive from one of these types:

- **AuthorizeAttribute**. Extend this class to perform authorization logic based on the current user and the user's roles.

- **AuthorizationFilterAttribute**. Extend this class to perform synchronous authorization logic that is not necessarily based on the current user or role.
- **IAuthorizationFilter**. Implement this interface to perform asynchronous authorization logic; for example, if your authorization logic makes asynchronous I/O or network calls. (If your authorization logic is CPU-bound, it is simpler to derive from **AuthorizationFilterAttribute**, because then you don't need to write an asynchronous method.)

The following diagram shows the class hierarchy for the **AuthorizeAttribute** class.

Authorization Inside a Controller Action

In some cases, you might allow a request to proceed, but change the behavior based on the principal. For example, the information that you return might change depending on the user's role. Within a controller method, you can get the current principal from the **ApiController.User** property.

```
public HttpResponseMessage Get()
{
    if (User.IsInRole("Administrators"))
    {
        // ...
    }
}
```

Secure a Web API with Individual Accounts and Local Login in ASP.NET Web API 2.2

2/20/2020 • 11 minutes to read • Edit Online

by Mike Wasson

Download Sample App

This topic shows how to secure a web API using OAuth2 to authenticate against a membership database.

Software versions used in the tutorial

- Visual Studio 2013 Update 3
- Web API 2.2
- ASP.NET Identity 2.1

In Visual Studio 2013, the Web API project template gives you three options for authentication:

- **Individual accounts.** The app uses a membership database.
- **Organizational accounts.** Users sign in with their Azure Active Directory, Office 365, or on-premise Active Directory credentials.
- **Windows authentication.** This option is intended for Intranet applications, and uses the Windows Authentication IIS module.

For more details about these options, see Creating ASP.NET Web Projects in Visual Studio 2013.

Individual accounts provide two ways for a user to log in:

- **Local login**. The user registers at the site, entering a username and password. The app stores the password hash in the membership database. When the user logs in, the ASP.NET Identity system verifies the password.
- **Social login**. The user signs in with an external service, such as Facebook, Microsoft, or Google. The app still creates an entry for the user in the membership database, but does not store any credentials. The user authenticates by signing into the external service.

This article looks at the local login scenario. For both local and social login, Web API uses OAuth2 to authenticate requests. However, the credential flows are different for local and social login.

In this article, I'll demonstrate a simple app that lets the user log in and send authenticated AJAX calls to a web API. You can download the sample code here. The readme describes how to create the sample from scratch in Visual Studio.

The sample app uses Knockout.js for data-binding and jQuery for sending AJAX requests. I'll be focusing on the AJAX calls, so you don't need to know Knockout.js for this article.

Along the way, I'll describe:

- What the app is doing on the client side.
- What's happening on the server.
- The HTTP traffic in the middle.

First, we need to define some OAuth2 terminology.

- *Resource*. Some piece of data that can be protected.
- *Resource server*. The server that hosts the resource.
- *Resource owner*. The entity that can grant permission to access a resource. (Typically the user.)
- *Client*. The app that wants access to the resource. In this article, the client is a web browser.
- *Access token*. A token that grants access to a resource.
- *Bearer token*. A particular type of access token, with the property that anyone can use the token. In other words, a client doesn't need a cryptographic key or other secret to use a bearer token. For that reason, bearer tokens should only be used over a HTTPS, and should have relatively short expiration times.
- *Authorization server*. A server that gives out access tokens.

An application can act as both authorization server and resource server. The Web API project template follows this pattern.

Local Login Credential Flow

For local login, Web API uses the resource owner password flow defined in OAuth2.

1. The user enters a name and password into the client.

2. The client sends these credentials to the authorization server.
3. The authorization server authenticates the credentials and returns an access token.
4. To access a protected resource, the client includes the access token in the Authorization header of the HTTP request.

When you select **Individual accounts** in the Web API project template, the project includes an authorization server that validates user credentials and issues tokens. The following diagram shows the same credential flow in terms of Web API components.

In this scenario, Web API controllers act as resource servers. An authentication filter validates access tokens, and the **[Authorize]** attribute is used to protect a resource. When a controller or action has the **[Authorize]** attribute, all requests to that controller or action must be authenticated. Otherwise, authorization is denied, and Web API returns a 401 (Unauthorized) error.

The authorization server and the authentication filter both call into an OWIN middleware component that handles the details of OAuth2. I'll describe the design in more detail later in this tutorial.

Sending an Unauthorized Request

To get started, run the app and click the **Call API** button. When the request completes, you should see an error message in the **Result** box. That's because the request does not contain an access token, so the request is unauthorized.

The **Call API** button sends an AJAX request to ~/api/values, which invokes a Web API controller action. Here is the section of JavaScript code that sends the AJAX request. In the sample app, all of the JavaScript app code is located in the Scripts\app.js file.

```
// If we already have a bearer token, set the Authorization header.
var token = sessionStorage.getItem(tokenKey);
var headers = {};
if (token) {
    headers.Authorization = 'Bearer ' + token;
}

$.ajax({
    type: 'GET',
    url: 'api/values/1',
    headers: headers
}).done(function (data) {
    self.result(data);
}).fail(showError);
```

Until the user logs in, there is no bearer token, and therefore no Authorization header in the request. This causes the request to return a 401 error.

Here is the HTTP request. (I used Fiddler to capture the HTTP traffic.)

```
GET https://localhost:44305/api/values HTTP/1.1
Host: localhost:44305
User-Agent: Mozilla/5.0 (Windows NT 6.3; WOW64; rv:32.0) Gecko/20100101 Firefox/32.0
Accept: */*
Accept-Language: en-US,en;q=0.5
X-Requested-With: XMLHttpRequest
Referer: https://localhost:44305/
```

HTTP response:

```
HTTP/1.1 401 Unauthorized
Content-Type: application/json; charset=utf-8
Server: Microsoft-IIS/8.0
WWW-Authenticate: Bearer
Date: Tue, 30 Sep 2014 21:54:43 GMT
Content-Length: 61

{"Message":"Authorization has been denied for this request."}
```

Notice that the response includes a Www-Authenticate header with the challenge set to Bearer. That indicates the server expects a bearer token.

Register a User

In the **Register** section of the app, enter an email and password, and click the **Register** button.

You don't need to use a valid email address for this sample, but a real app would confirm the address. (See Create a secure ASP.NET MVC 5 web app with log in, email confirmation and password reset.) For the password, use something like "Password1!", with an upper case letter, lower case letter, number, and non-alpha-numeric character. To keep the app simple, I left out client-side validation, so if there is a problem with the password format, you'll get a 400 (Bad Request) error.

The **Register** button sends a POST request to ~/api/Account/Register/. The request body is a JSON object that holds the name and password. Here is the JavaScript code that sends the request:

```
var data = {
    Email: self.registerEmail(),
    Password: self.registerPassword(),
    ConfirmPassword: self.registerPassword2()
};

$.ajax({
    type: 'POST',
    url: '/api/Account/Register',
    contentType: 'application/json; charset=utf-8',
    data: JSON.stringify(data)
}).done(function (data) {
    self.result("Done!");
}).fail(showError);
```

HTTP request:

```
POST https://localhost:44305/api/Account/Register HTTP/1.1
Host: localhost:44305
User-Agent: Mozilla/5.0 (Windows NT 6.3; WOW64; rv:32.0) Gecko/20100101 Firefox/32.0
Accept: */*
Content-Type: application/json; charset=utf-8
X-Requested-With: XMLHttpRequest
Referer: https://localhost:44305/
Content-Length: 84

{"Email":"alice@example.com","Password":"Password1!","ConfirmPassword":"Password1!"}
```

HTTP response:

```
HTTP/1.1 200 OK
Server: Microsoft-IIS/8.0
Date: Wed, 01 Oct 2014 00:57:58 GMT
Content-Length: 0
```

This request is handled by the `AccountController` class. Internally, `AccountController` uses ASP.NET Identity to manage the membership database.

If you run the app locally from Visual Studio, user accounts are stored in LocalDB, in the AspNetUsers table. To view the tables in Visual Studio, click the **View** menu, select **Server Explorer**, then expand **Data Connections**.

Get an Access Token

So far we have not done any OAuth, but now we'll see the OAuth authorization server in action, when we request

an access token. In the **Log In** area of the sample app, enter the email and password and click **Log In**.

The **Log In** button sends a request to the token endpoint. The body of the request contains the following form-url-encoded data:

- grant_type: "password"
- username: <the user's email>
- password: <password>

Here is the JavaScript code that sends the AJAX request:

```
var loginData = {
    grant_type: 'password',
    username: self.loginEmail(),
    password: self.loginPassword()
};

$.ajax({
    type: 'POST',
    url: '/Token',
    data: loginData
}).done(function (data) {
    self.user(data.userName);
    // Cache the access token in session storage.
    sessionStorage.setItem(tokenKey, data.access_token);
}).fail(showError);
```

If the request succeeds, the authorization server returns an access token in the response body. Notice that we store the token in session storage, to use later when sending requests to the API. Unlike some forms of authentication (such as cookie-based authentication), the browser will not automatically include the access token in subsequent requests. The application must do so explicitly. That's a good thing, because it limits CSRF vulnerabilities.

HTTP request:

```
POST https://localhost:44305/Token HTTP/1.1
Host: localhost:44305
User-Agent: Mozilla/5.0 (Windows NT 6.3; WOW64; rv:32.0) Gecko/20100101 Firefox/32.0
Accept: */*
Content-Type: application/x-www-form-urlencoded; charset=UTF-8
X-Requested-With: XMLHttpRequest
Referer: https://localhost:44305/
Content-Length: 68

grant_type=password&username=alice%40example.com&password=Password1!
```

You can see that the request contains the user's credentials. You *must* use HTTPS to provide transport layer security.

HTTP response:

```
HTTP/1.1 200 OK
Content-Length: 669
Content-Type: application/json;charset=UTF-8
Server: Microsoft-IIS/8.0
Date: Wed, 01 Oct 2014 01:22:36 GMT

{
  "access_token":"imSXTs2OqSrGWzsFQhIXziFCO3rF...",
  "token_type":"bearer",
  "expires_in":1209599,
  "userName":"alice@example.com",
  ".issued":"Wed, 01 Oct 2014 01:22:33 GMT",
  ".expires":"Wed, 15 Oct 2014 01:22:33 GMT"
}
```

For readability, I indented the JSON and truncated the access token, which is a quite long.

The `access_token`, `token_type`, and `expires_in` properties are defined by the OAuth2 spec. The other properties (`userName`, `.issued`, and `.expires`) are just for informational purposes. You can find the code that adds those additional properties in the `TokenEndpoint` method, in the /Providers/ApplicationOAuthProvider.cs file.

Send an Authenticated Request

Now that we have a bearer token, we can make an authenticated request to the API. This is done by setting the Authorization header in the request. Click the **Call API** button again to see this.

HTTP request:

```
GET https://localhost:44305/api/values/1 HTTP/1.1
Host: localhost:44305
User-Agent: Mozilla/5.0 (Windows NT 6.3; WOW64; rv:32.0) Gecko/20100101 Firefox/32.0
Accept: */*
Authorization: Bearer imSXTs2OqSrGWzsFQhIXziFCO3rF...
X-Requested-With: XMLHttpRequest
```

HTTP response:

```
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Server: Microsoft-IIS/8.0
Date: Wed, 01 Oct 2014 01:41:29 GMT
Content-Length: 27

"Hello, alice@example.com."
```

Log Out

Because the browser does not cache the credentials or the access token, logging out is simply a matter of "forgetting" the token, by removing it from session storage:

```
self.logout = function () {
    sessionStorage.removeItem(tokenKey)
}
```

Understanding the Individual Accounts Project Template

When you select **Individual Accounts** in the ASP.NET Web Application project template, the project includes:

- An OAuth2 authorization server.
- A Web API endpoint for managing user accounts
- An EF model for storing user accounts.

Here are the main application classes that implement these features:

- `AccountController`. Provides a Web API endpoint for managing user accounts. The `Register` action is the only one that we used in this tutorial. Other methods on the class support password reset, social logins, and other functionality.
- `ApplicationUser`, defined in /Models/IdentityModels.cs. This class is the EF model for user accounts in the membership database.
- `ApplicationUserManager`, defined in /App_Start/IdentityConfig.cs This class derives from UserManager and performs operations on user accounts, such as creating a new user, verifying passwords, and so forth, and automatically persists changes to the database.
- `ApplicationOAuthProvider`. This object plugs into the OWIN middleware, and processes events raised by the middleware. It derives from OAuthAuthorizationServerProvider.

Configuring the Authorization Server

In StartupAuth.cs, the following code configures the OAuth2 authorization server.

```
PublicClientId = "self";
OAuthOptions = new OAuthAuthorizationServerOptions
{
    TokenEndpointPath = new PathString("/Token"),
    Provider = new ApplicationOAuthProvider(PublicClientId),
    AuthorizeEndpointPath = new PathString("/api/Account/ExternalLogin"),
    AccessTokenExpireTimeSpan = TimeSpan.FromDays(14),
    // Note: Remove the following line before you deploy to production:
    AllowInsecureHttp = true
};

// Enable the application to use bearer tokens to authenticate users
app.UseOAuthBearerTokens(OAuthOptions);
```

The `TokenEndpointPath` property is the URL path to the authorization server endpoint. That's the URL that app uses to get the bearer tokens.

The `Provider` property specifies a provider that plugs into the OWIN middleware, and processes events raised by the middleware.

Here is the basic flow when the app wants to get a token:

1. To get an access token, the app sends a request to ~/Token.
2. The OAuth middleware calls `GrantResourceOwnerCredentials` on the provider.
3. The provider calls the `ApplicationUserManager` to validate the credentials and create a claims identity.
4. If that succeeds, the provider creates an authentication ticket, which is used to generate the token.

The OAuth middleware doesn't know anything about the user accounts. The provider communicates between the middleware and ASP.NET Identity. For more information about implementing the authorization server, see OWIN OAuth 2.0 Authorization Server.

Configuring Web API to use Bearer Tokens

In the `WebApiConfig.Register` method, the following code sets up authentication for the Web API pipeline:

```
config.SuppressDefaultHostAuthentication();
config.Filters.Add(new HostAuthenticationFilter(OAuthDefaults.AuthenticationType));
```

The **HostAuthenticationFilter** class enables authentication using bearer tokens.

The **SuppressDefaultHostAuthentication** method tells Web API to ignore any authentication that happens before the request reaches the Web API pipeline, either by IIS or by OWIN middleware. That way, we can restrict Web API to authenticate only using bearer tokens.

> **NOTE**
> In particular, the MVC portion of your app might use forms authentication, which stores credentials in a cookie. Cookie-based authentication requires the use of anti-forgery tokens, to prevent CSRF attacks. That's a problem for web APIs, because there is no convenient way for the web API to send the anti-forgery token to the client. (For more background on this issue, see Preventing CSRF Attacks in Web API.) Calling **SuppressDefaultHostAuthentication** ensures that Web API is not vulnerable to CSRF attacks from credentials stored in cookies.

When the client requests a protected resource, here is what happens in the Web API pipeline:

1. The **HostAuthentication** filter calls the OAuth middleware to validate the token.
2. The middleware converts the token into a claims identity.
3. At this point, the request is *authenticated* but not *authorized*.
4. The authorization filter examines the claims identity. If the claims authorize the user for that resource, the request is authorized. By default, the **[Authorize]** attribute will authorize any request that is authenticated. However, you can authorize by role or by other claims. For more information, see Authentication and Authorization in Web API.
5. If the previous steps are successful, the controller returns the protected resource. Otherwise, the client receives a 401 (Unauthorized) error.

External Authentication Services with ASP.NET Web API (C#)

2/20/2020 • 16 minutes to read • Edit Online

Visual Studio 2017 and ASP.NET 4.7.2 expand the security options for Single Page Applications (SPA) and Web API services to integrate with external authentication services, which include several OAuth/OpenID and social media authentication services: Microsoft Accounts, Twitter, Facebook, and Google.

In this Walkthrough

- Using External Authentication Services
- Creating the Sample Web Application
- Enabling Facebook Authentication
- Enabling Google Authentication
- Enabling Microsoft Authentication
- Enabling Twitter Authentication
- Additional Information
  - Combining External Authentication Services
  - Configuring IIS Express to use a Fully Qualified Domain Name
  - How to Obtain your Application Settings for Microsoft Authentication
  - Optional: Disable Local Registration

Prerequisites

To follow the examples in this walkthrough, you need to have the following:

- Visual Studio 2017
- A developer account with the application identifier and secret key for one of the following social media authentication services:
  - Microsoft Accounts (https://go.microsoft.com/fwlink/?LinkID=144070)
  - Twitter (https://dev.twitter.com/)
  - Facebook (https://developers.facebook.com/)
  - Google (https://developers.google.com/)

Using External Authentication Services

The abundance of external authentication services that are currently available to web developers help to reduce development time when creating new web applications. Web users typically have several existing accounts for popular web services and social media websites, therefore when a web application implements the authentication services from an external web service or social media website, it saves the development time that would have been spent creating an authentication implementation. Using an external authentication service saves end users from having to create another account for your web application, and also from having to remember another username and password.

In the past, developers have had two choices: create their own authentication implementation, or learn how to

integrate an external authentication service into their applications. At the most basic level, the following diagram illustrates a simple request flow for a user agent (web browser) that is requesting information from a web application that is configured to use an external authentication service:

In the preceding diagram, the user agent (or web browser in this example) makes a request to a web application, which redirects the web browser to an external authentication service. The user agent sends its credentials to the external authentication service, and if the user agent has successfully authenticated, the external authentication service will redirect the user agent to the original web application with some form of token which the user agent will send to the web application. The web application will use the token to verify that the user agent has been successfully authenticated by the external authentication service, and the web application may use the token to gather more information about the user agent. Once the application is done processing the user agent's information, the web application will return the appropriate response to the user agent based on its authorization settings.

In this second example, the user agent negotiates with the web application and external authorization server, and the web application performs additional communication with the external authorization server to retrieve additional information about the user agent:

Visual Studio 2017 and ASP.NET 4.7.2 make integration with external authentication services easier for developers by providing built-in integration for the following authentication services:

- Facebook
- Google
- Microsoft Accounts (Windows Live ID accounts)
- Twitter

The examples in this walkthrough will demonstrate how to configure each of the supported external authentication services by using the new ASP.NET Web Application template that ships with Visual Studio 2017.

> **NOTE**
>
> If necessary, you may need to add your FQDN to the settings for your external authentication service. This requirement is based on security constraints for some external authentication services which require the FQDN in your application settings to match the FQDN that is used by your clients. (The steps for this will vary greatly for each external authentication service; you will need to consult the documentation for each external authentication service to see if this is required and how to configure these settings.) If you need to configure IIS Express to use an FQDN for testing this environment, see the Configuring IIS Express to use a Fully Qualified Domain Name section later in this walkthrough.

Create a Sample Web Application

The following steps will lead you through creating a sample application by using the ASP.NET Web Application template, and you will use this sample application for each of the external authentication services later in this

walkthrough.

Start Visual Studio 2017 and select **New Project** from the Start page. Or, from the **File** menu, select **New** and then **Project**.

When the **New Project** dialog box is displayed, select **Installed** and expand **Visual C#**. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET Web Application (.Net Framework)**. Enter a name for your project and click **OK**.

When the **New ASP.NET Project** is displayed, select the **Single Page Application** template and click **Create Project**.

Wait as Visual Studio 2017 creates your project.

When Visual Studio 2017 has finished creating your project, open the *Startup.Auth.cs* file that is located in the **App_Start** folder.

When you first create the project, none of the external authentication services are enabled in *Startup.Auth.cs* file;

the following illustrates what your code might resemble, with the sections highlighted for where you would enable an external authentication service and any relevant settings in order to use Microsoft Accounts, Twitter, Facebook, or Google authentication with your ASP.NET application:

```
using System;
using Microsoft.AspNet.Identity;
using Microsoft.AspNet.Identity.EntityFramework;
using Microsoft.AspNet.Identity.Owin;
using Microsoft.Owin;
using Microsoft.Owin.Security.Cookies;
using Microsoft.Owin.Security.DataProtection;
using Microsoft.Owin.Security.Google;
using Microsoft.Owin.Security.OAuth;
using Owin;
using WebApplication1.Models;
using WebApplication1.Providers;

namespace WebApplication1
{
    public partial class Startup
    {
        // Enable the application to use OAuthAuthorization. You can then secure your Web APIs
        static Startup()
        {
            PublicClientId = "web";

            OAuthOptions = new OAuthAuthorizationServerOptions
            {
                TokenEndpointPath = new PathString("/Token"),
                AuthorizeEndpointPath = new PathString("/Account/Authorize"),
                Provider = new ApplicationOAuthProvider(PublicClientId),
                AccessTokenExpireTimeSpan = TimeSpan.FromDays(14),
                AllowInsecureHttp = true
            };
        }

        public static OAuthAuthorizationServerOptions OAuthOptions { get; private set; }

        public static string PublicClientId { get; private set; }

        // For more information on configuring authentication, please visit https://go.microsoft.com/fwlink/?
LinkId=301864
        public void ConfigureAuth(IAppBuilder app)
        {
            // Configure the db context, user manager and signin manager to use a single instance per request
            app.CreatePerOwinContext(ApplicationDbContext.Create);
            app.CreatePerOwinContext<ApplicationUserManager>(ApplicationUserManager.Create);
            app.CreatePerOwinContext<ApplicationSignInManager>(ApplicationSignInManager.Create);

            // Enable the application to use a cookie to store information for the signed in user
            app.UseCookieAuthentication(new CookieAuthenticationOptions
            {
                AuthenticationType = DefaultAuthenticationTypes.ApplicationCookie,
                LoginPath = new PathString("/Account/Login"),
                Provider = new CookieAuthenticationProvider
                {
                    // Enables the application to validate the security stamp when the user logs in.
                    // This is a security feature which is used when you change a password or add an external
login to your account.
                    OnValidateIdentity = SecurityStampValidator.OnValidateIdentity<ApplicationUserManager,
ApplicationUser>(
                        validateInterval: TimeSpan.FromMinutes(20),
                        regenerateIdentity: (manager, user) => user.GenerateUserIdentityAsync(manager))
                }
            });
            // Use a cookie to temporarily store information about a user logging in with a third party login
provider
```

```
            app.UseExternalSignInCookie(DefaultAuthenticationTypes.ExternalCookie);

            // Enables the application to temporarily store user information when they are verifying the
second factor in the two-factor authentication process.
            app.UseTwoFactorSignInCookie(DefaultAuthenticationTypes.TwoFactorCookie,
TimeSpan.FromMinutes(5));

            // Enables the application to remember the second login verification factor such as phone or
email.
            // Once you check this option, your second step of verification during the login process will be
remembered on the device where you logged in from.
            // This is similar to the RememberMe option when you log in.
            app.UseTwoFactorRememberBrowserCookie(DefaultAuthenticationTypes.TwoFactorRememberBrowserCookie);

            // Enable the application to use bearer tokens to authenticate users
            app.UseOAuthBearerTokens(OAuthOptions);

            // Uncomment the following lines to enable logging in with third party login providers
            //app.UseMicrosoftAccountAuthentication(
            //    clientId: "",
            //    clientSecret: "");

            //app.UseTwitterAuthentication(
            //    consumerKey: "",
            //    consumerSecret: "");

            //app.UseFacebookAuthentication(
            //    appId: "",
            //    appSecret: "");

            //app.UseGoogleAuthentication(new GoogleOAuth2AuthenticationOptions()
            //{
            //    ClientId = "",
            //    ClientSecret = ""
            //});
        }
    }
}
```

When you press F5 to build and debug your web application, it will display a login screen where you will see that no external authentication services have been defined.

In the following sections, you will learn how to enable each of the external authentication services that are

provided with ASP.NET in Visual Studio 2017.

Enabling Facebook authentication

Using Facebook authentication requires you to create a Facebook developer account, and your project will require an application ID and secret key from Facebook in order to function. For information about creating a Facebook developer account and obtaining your application ID and secret key, see https://go.microsoft.com/fwlink/?LinkID=252166.

Once you have obtained your application ID and secret key, use the following steps to enable Facebook authentication for your web application:

1. When your project is open in Visual Studio 2017, open the *Startup.Auth.cs* file.
2. Locate the Facebook authentication section of code:

```
// Uncomment the following lines to enable logging in with third party login providers
//app.UseMicrosoftAccountAuthentication(
//    clientId: "",
//    clientSecret: "");

//app.UseTwitterAuthentication(
//    consumerKey: "",
//    consumerSecret: "");

//app.UseFacebookAuthentication(
//    appId: "",
//    appSecret: "");

//app.UseGoogleAuthentication(new GoogleOAuth2AuthenticationOptions()
//{
//    ClientId = "",
//    ClientSecret = ""
//});
```

3. Remove the "//" characters to uncomment the highlighted lines of code, and then add your application ID and secret key. Once you have added those parameters, you can recompile your project:

```
// Uncomment the following lines to enable logging in with third party login providers
//app.UseMicrosoftAccountAuthentication(
//    clientId: "",
//    clientSecret: "");

//app.UseTwitterAuthentication(
//   consumerKey: "",
//   consumerSecret: "");

//app.UseFacebookAuthentication(
//   appId: "426f62526f636b73",
//   appSecret: "");

//app.UseGoogleAuthentication();
```

4. When you press F5 to open your web application in your web browser, you will see that Facebook has been defined as an external authentication service:

5. When you click the **Facebook** button, your browser will be redirected to the Facebook login page:

6. After you enter your Facebook credentials and click **Log in**, your web browser will be redirected back to your web application, which will prompt you for the **User name** that you want to associate with your Facebook account:

7. After you have entered your user name and clicked the **Sign up** button, your web application will display the default **home page** for your Facebook account:

Enabling Google Authentication

Using Google authentication requires you to create a Google developer account, and your project will require an application ID and secret key from Google in order to function. For information about creating a Google developer account and obtaining your application ID and secret key, see https://developers.google.com.

To enable Google authentication for your web application, use the following steps:

1. When your project is open in Visual Studio 2017, open the *Startup.Auth.cs* file.

2. Locate the Google authentication section of code:

```
// Uncomment the following lines to enable logging in with third party login providers
//app.UseMicrosoftAccountAuthentication(
//    clientId: "",
//    clientSecret: "");

//app.UseTwitterAuthentication(
//    consumerKey: "",
//    consumerSecret: "");

//app.UseFacebookAuthentication(
//    appId: "",
//    appSecret: "");

//app.UseGoogleAuthentication(new GoogleOAuth2AuthenticationOptions()
//{
//    ClientId = "",
//    ClientSecret = ""
//});
```

3. Remove the "//" characters to uncomment the highlighted lines of code, and then add your application ID and secret key. Once you have added those parameters, you can recompile your project:

```
// Uncomment the following lines to enable logging in with third party login providers
//app.UseMicrosoftAccountAuthentication(
//    clientId: "",
//    clientSecret: "");

//app.UseTwitterAuthentication(
//   consumerKey: "",
//   consumerSecret: "");

//app.UseFacebookAuthentication(
//   appId: "",
//   appSecret: "");

app.UseGoogleAuthentication(new GoogleOAuth2AuthenticationOptions()
{
    ClientId = "477522346600.apps.googleusercontent.com",
    ClientSecret = "gobkdpbocikdfbnfahjladnetpdkvmic"
});
```

4. When you press F5 to open your web application in your web browser, you will see that Google has been defined as an external authentication service:

5. When you click the **Google** button, your browser will be redirected to the Google login page:

6. After you enter your Google credentials and click **Sign in**, Google will prompt you to verify that your web application has permissions to access your Google account:

7. When you click **Accept**, your web browser will be redirected back to your web application, which will prompt you for the **User name** that you want to associate with your Google account:

8. After you have entered your user name and clicked the **Sign up** button, your web application will display the default **home page** for your Google account:

Enabling Microsoft Authentication

Microsoft authentication requires you to create a developer account, and it requires a client ID and client secret in order to function. For information about creating a Microsoft developer account and obtaining your client ID and client secret, see https://go.microsoft.com/fwlink/?LinkID=144070.

Once you have obtained your consumer key and consumer secret, use the following steps to enable Microsoft authentication for your web application:

1. When your project is open in Visual Studio 2017, open the *Startup.Auth.cs* file.
2. Locate the Microsoft authentication section of code:

```
// Uncomment the following lines to enable logging in with third party login providers
//app.UseMicrosoftAccountAuthentication(
//    clientId: "",
//    clientSecret: "");

//app.UseTwitterAuthentication(
//   consumerKey: "",
//   consumerSecret: "");

//app.UseFacebookAuthentication(
//   appId: "",
//   appSecret: "");

//app.UseGoogleAuthentication(new GoogleOAuth2AuthenticationOptions()
//{
//    ClientId = "",
//    ClientSecret = ""
//});
```

3. Remove the "//" characters to uncomment the highlighted lines of code, and then add your client ID and client secret. Once you have added those parameters, you can recompile your project:

```
// Uncomment the following lines to enable logging in with third party login providers
app.UseMicrosoftAccountAuthentication(
    clientId: "426f62526f636b73",
    clientSecret: "57686f6120447564652c2049495320526f636b73");

//app.UseTwitterAuthentication(
//   consumerKey: "",
//   consumerSecret: "");

//app.UseFacebookAuthentication(
//   appId: "",
//   appSecret: "");

//app.UseGoogleAuthentication(new GoogleOAuth2AuthenticationOptions()
//{
//    ClientId = "",
//    ClientSecret = ""
//});
```

4. When you press F5 to open your web application in your web browser, you will see that Microsoft has been defined as an external authentication service:

5. When you click the **Microsoft** button, your browser will be redirected to the Microsoft login page:

6. After you enter your Microsoft credentials and click **Sign in**, you will be prompted to verify that your web application has permissions to access your Microsoft account:

7. When you click **Yes**, your web browser will be redirected back to your web application, which will prompt you for the **User name** that you want to associate with your Microsoft account:

8. After you have entered your user name and clicked the **Sign up** button, your web application will display the default **home page** for your Microsoft account:

Enabling Twitter Authentication

Twitter authentication requires you to create a developer account, and it requires a consumer key and consumer secret in order to function. For information about creating a Twitter developer account and obtaining your consumer key and consumer secret, see https://go.microsoft.com/fwlink/?LinkID=252166.

Once you have obtained your consumer key and consumer secret, use the following steps to enable Twitter authentication for your web application:

1. When your project is open in Visual Studio 2017, open the *Startup.Auth.cs* file.

2. Locate the Twitter authentication section of code:

```
// Uncomment the following lines to enable logging in with third party login providers
//app.UseMicrosoftAccountAuthentication(
//    clientId: "",
//    clientSecret: "");

//app.UseTwitterAuthentication(
//   consumerKey: "",
//   consumerSecret: "");

//app.UseFacebookAuthentication(
//   appId: "",
//   appSecret: "");

//app.UseGoogleAuthentication(new GoogleOAuth2AuthenticationOptions()
//{
//    ClientId = "",
//    ClientSecret = ""
//});
```

3. Remove the "//" characters to uncomment the highlighted lines of code, and then add your consumer key and consumer secret. Once you have added those parameters, you can recompile your project:

```
// Uncomment the following lines to enable logging in with third party login providers
//app.UseMicrosoftAccountAuthentication(
//    clientId: "",
//    clientSecret: "");

app.UseTwitterAuthentication(
   consumerKey: "426f62526f636b73",
   consumerSecret: "57686f6120447564652c2049495320526f636b73");

//app.UseFacebookAuthentication(
//   appId: "",
//   appSecret: "");

//app.UseGoogleAuthentication(new GoogleOAuth2AuthenticationOptions()
//{
//    ClientId = "",
//    ClientSecret = ""
//});
```

4. When you press F5 to open your web application in your web browser, you will see that Twitter has been defined as an external authentication service:

5. When you click the **Twitter** button, your browser will be redirected to the Twitter login page:

6. After you enter your Twitter credentials and click **Authorize app**, your web browser will be redirected back to your web application, which will prompt you for the **User name** that you want to associate with your Twitter account:

7. After you have entered your user name and clicked the **Sign up** button, your web application will display the default **home page** for your Twitter account:

Additional Information

For additional information about creating applications that use OAuth and OpenID, see the following URLs:

- https://go.microsoft.com/fwlink/?LinkID=252166
- https://go.microsoft.com/fwlink/?LinkID=243995

Combining External Authentication Services

For greater flexibility, you can define multiple external authentication services at the same time - this allows your web application's users to use an account from any of the enabled external authentication services:

Configure IIS Express to use a fully qualified domain name

Some external authentication providers do not support testing your application by using an HTTP address like `http://localhost:port/`. To work around this issue, you can add a static Fully Qualified Domain Name (FQDN) mapping to your HOSTS file and configure your project options in Visual Studio 2017 to use the FQDN for testing/debugging. To do so, use the following steps:

- Add a static FQDN mapping your HOSTS file:
  1. Open an elevated command prompt in Windows.
  2. Type the following command:

     ```
     notepad %WinDir%\system32\drivers\etc\hosts
     ```

  3. Add an entry like the following to the HOSTS file:

     ```
     127.0.0.1 www.wingtiptoys.com
     ```

  4. Save and close your HOSTS file.
- Configure your Visual Studio project to use the FQDN:
  1. When your project is open in Visual Studio 2017, click the **Project** menu, and then select your project's properties. For example, you might select **WebApplication1 Properties**.
  2. Select the **Web** tab.
  3. Enter your FQDN for the **Project Url**. For example, you would enter `http://www.wingtiptoys.com` if that was the FQDN mapping that you added to your HOSTS file.
- Configure IIS Express to use the FQDN for your application:

1. Open an elevated command prompt in Windows.
2. Type the following command to change to your IIS Express folder:

   ```
   cd /d "%ProgramFiles%\IIS Express"
   ```

3. Type the following command to add the FQDN to your application:

   ```
   appcmd.exe set config -section:system.applicationHost/sites /+"
   [name='WebApplication1'].bindings.
   [protocol='http',bindingInformation='*:80:www.wingtiptoys.com']"
   /commit:apphost
   ```

   Where **WebApplication1** is the name of your project and **bindingInformation** contains the port number and FQDN that you want to use for your testing.

How to Obtain your Application Settings for Microsoft Authentication

Linking an application to Windows Live for Microsoft Authentication is a simple process. If you have not already linked an application to Windows Live, you can use the following steps:

1. Browse to https://go.microsoft.com/fwlink/?LinkID=144070 and enter your Microsoft account name and password when prompted, then click **Sign in**:
2. Select **Add an app** and enter the name of your application when prompted, and then click **Create**:

3. Select your app under **Name** and its application properties page appears.
4. Enter the redirect domain for your application. Copy the **Application ID** and, under **Application Secrets**, select **Generate Password**. Copy the password that appears. The application ID and password are your client ID and client secret. Select **Ok** and then **Save**.

Optional: Disable Local Registration

The current ASP.NET local registration functionality does not prevent automated programs (bots) from creating member accounts; for example, by using a bot-prevention and validation technology like CAPTCHA. Because of this, you should remove the local login form and registration link on the login page. To do so, open the *_Login.cshtml* page in your project, and then comment out the lines for the local login panel and the registration link. The resulting page should look like the following code sample:

```
<!-- ko with: login -->
<hgroup class="title">
    <h1>Log in</h1>
</hgroup>
<div class="row-fluid">
    @*<section class="span7">
        <form>
            <fieldset class="form-horizontal">
                <legend>Use a local account to log in.</legend>
                <ul class="text-error" data-bind="foreach: errors">
                    <li data-bind="text: $data"></li>
                </ul>
                <div class="control-group">
                    <label for="UserName" class="control-label">User name</label>
                    <div class="controls">
                        <input type="text" name="UserName" data-bind="value: userName, hasFocus: true" />
                        <span class="text-error" data-bind="visible: userName.hasError, text:
userName.errorMessage"></span>
                    </div>
                </div>
                <div class="control-group">
                    <label for="Password" class="control-label">Password</label>
                    <div class="controls">
                        <input type="password" name="Password" data-bind="value: password" />
                        <span class="text-error" data-bind="visible: password.hasError, text:
password.errorMessage"></span>
                    </div>
                </div>
                <div class="control-group">
                    <div class="controls">
                        <label class="checkbox">
                            <input type="checkbox" name="RememberMe" data-bind="checked: rememberMe" />
                            <label for="RememberMe">Remember me?</label>
                        </label>
                    </div>
                </div>
                <div class="form-actions no-color">
                    <button type="submit" class="btn" data-bind="click: login, disable: loggingIn">Log
in</button>
```

```
                </div>
                <p><a href="#" data-bind="click: register">Register</a> if you don't have a local account.
</p>
            </fieldset>
        </form>
    </section>*@
    <section class="span5">
        <h2>Log in using another service</h2>
        <div data-bind="visible: loadingExternalLogin">Loading...</div>
        <div data-bind="visible: !loadingExternalLogin()">
            <div class="message-info" data-bind="visible: !hasExternalLogin()">
                <p>
                    There are no external authentication services configured. See <a
href="https://go.microsoft.com/fwlink/?LinkId=252166">this article</a>
                    for details on setting up this ASP.NET application to support logging in via external
services.
                </p>
            </div>
            <form data-bind="visible: hasExternalLogin">
                <fieldset class="form-horizontal">
                    <legend>Use another service to log in.</legend>
                    <p data-bind="foreach: externalLoginProviders">
                        <button type="submit" class="btn" data-bind="text: name, attr: { title: 'Log in using
your ' + name() + ' account' }, click: login"></button>
                    </p>
                </fieldset>
            </form>
        </div>
    </section>
</div>
<!-- /ko -->
```

Once the local login panel and the registration link have been disabled, your login page will only display the external authentication providers that you have enabled:

Preventing Cross-Site Request Forgery (CSRF) Attacks in ASP.NET MVC Application

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson

Cross-Site Request Forgery (CSRF) is an attack where a malicious site sends a request to a vulnerable site where the user is currently logged in

Here is an example of a CSRF attack:

1. A user logs into `www.example.com` using forms authentication.
2. The server authenticates the user. The response from the server includes an authentication cookie.
3. Without logging out, the user visits a malicious web site. This malicious site contains the following HTML form:

   ```
   <h1>You Are a Winner!</h1>
     <form action="http://example.com/api/account" method="post">
       <input type="hidden" name="Transaction" value="withdraw" />
       <input type="hidden" name="Amount" value="1000000" />
     <input type="submit" value="Click Me"/>
   </form>
   ```

   Notice that the form action posts to the vulnerable site, not to the malicious site. This is the "cross-site" part of CSRF.
4. The user clicks the submit button. The browser includes the authentication cookie with the request.
5. The request runs on the server with the user's authentication context, and can do anything that an authenticated user is allowed to do.

Although this example requires the user to click the form button, the malicious page could just as easily run a script that submits the form automatically. Moreover, using SSL does not prevent a CSRF attack, because the malicious site can send an "https://" request.

Typically, CSRF attacks are possible against web sites that use cookies for authentication, because browsers send all relevant cookies to the destination web site. However, CSRF attacks are not limited to exploiting cookies. For example, Basic and Digest authentication are also vulnerable. After a user logs in with Basic or Digest authentication. the browser automatically sends the credentials until the session ends.

Anti-Forgery Tokens

To help prevent CSRF attacks, ASP.NET MVC uses anti-forgery tokens, also called *request verification tokens*.

1. The client requests an HTML page that contains a form.
2. The server includes two tokens in the response. One token is sent as a cookie. The other is placed in a hidden form field. The tokens are generated randomly so that an adversary cannot guess the values.
3. When the client submits the form, it must send both tokens back to the server. The client sends the cookie token as a cookie, and it sends the form token inside the form data. (A browser client automatically does this when the user submits the form.)
4. If a request does not include both tokens, the server disallows the request.

Here is an example of an HTML form with a hidden form token:

```
<form action="/Home/Test" method="post">
    <input name="__RequestVerificationToken" type="hidden"
           value="6fGBtLZmVBZ59oUad1Fr33BuPxANKY9q3Srr5y[...]" />
    <input type="submit" value="Submit" />
</form>
```

Anti-forgery tokens work because the malicious page cannot read the user's tokens, due to same-origin policies. (Same-origin policies prevent documents hosted on two different sites from accessing each other's content. So in the earlier example, the malicious page can send requests to example.com, but it cannot read the response.)

To prevent CSRF attacks, use anti-forgery tokens with any authentication protocol where the browser silently sends credentials after the user logs in. This includes cookie-based authentication protocols, such as forms authentication, as well as protocols such as Basic and Digest authentication.

You should require anti-forgery tokens for any nonsafe methods (POST, PUT, DELETE). Also, make sure that safe methods (GET, HEAD) do not have any side effects. Moreover, if you enable cross-domain support, such as CORS or JSONP, then even safe methods like GET are potentially vulnerable to CSRF attacks, allowing the attacker to read potentially sensitive data.

Anti-Forgery Tokens in ASP.NET MVC

To add the anti-forgery tokens to a Razor page, use the **HtmlHelper.AntiForgeryToken** helper method:

```
@using (Html.BeginForm("Manage", "Account")) {
    @Html.AntiForgeryToken()
}
```

This method adds the hidden form field and also sets the cookie token.

Anti-CSRF and AJAX

The form token can be a problem for AJAX requests, because an AJAX request might send JSON data, not HTML form data. One solution is to send the tokens in a custom HTTP header. The following code uses Razor syntax to generate the tokens, and then adds the tokens to an AJAX request. The tokens are generated at the server by calling **AntiForgery.GetTokens**.

```
<script>
    @functions{
        public string TokenHeaderValue()
        {
            string cookieToken, formToken;
            AntiForgery.GetTokens(null, out cookieToken, out formToken);
            return cookieToken + ":" + formToken;
        }
    }

    $.ajax("api/values", {
        type: "post",
        contentType: "application/json",
        data: {  }, // JSON data goes here
        dataType: "json",
        headers: {
            'RequestVerificationToken': '@TokenHeaderValue()'
        }
    });
</script>
```

When you process the request, extract the tokens from the request header. Then call the **AntiForgery.Validate** method to validate the tokens. The **Validate** method throws an exception if the tokens are not valid.

```
void ValidateRequestHeader(HttpRequestMessage request)
{
    string cookieToken = "";
    string formToken = "";

    IEnumerable<string> tokenHeaders;
    if (request.Headers.TryGetValues("RequestVerificationToken", out tokenHeaders))
    {
        string[] tokens = tokenHeaders.First().Split(':');
        if (tokens.Length == 2)
        {
            cookieToken = tokens[0].Trim();
            formToken = tokens[1].Trim();
        }
    }
    AntiForgery.Validate(cookieToken, formToken);
}
```

Enable cross-origin requests in ASP.NET Web API 2

2/20/2020 • 12 minutes to read • Edit Online

by Mike Wasson

Browser security prevents a web page from making AJAX requests to another domain. This restriction is called the *same-origin policy*, and prevents a malicious site from reading sensitive data from another site. However, sometimes you might want to let other sites call your web API.

Cross Origin Resource Sharing (CORS) is a W3C standard that allows a server to relax the same-origin policy. Using CORS, a server can explicitly allow some cross-origin requests while rejecting others. CORS is safer and more flexible than earlier techniques such as JSONP. This tutorial shows how to enable CORS in your Web API application.

Software used in the tutorial

- Visual Studio
- Web API 2.2

Introduction

This tutorial demonstrates CORS support in ASP.NET Web API. We'll start by creating two ASP.NET projects – one called "WebService", which hosts a Web API controller, and the other called "WebClient", which calls WebService. Because the two applications are hosted at different domains, an AJAX request from WebClient to WebService is a cross-origin request.

What is "same origin"?

Two URLs have the same origin if they have identical schemes, hosts, and ports. (RFC 6454)

These two URLs have the same origin:

- `http://example.com/foo.html`
- `http://example.com/bar.html`

These URLs have different origins than the previous two:

- `http://example.net` - Different domain
- `http://example.com:9000/foo.html` - Different port
- `https://example.com/foo.html` - Different scheme
- `http://www.example.com/foo.html` - Different subdomain

> **NOTE**
>
> Internet Explorer does not consider the port when comparing origins.

Create the WebService project

> **NOTE**
>
> This section assumes you already know how to create Web API projects. If not, see Getting Started with ASP.NET Web API.

1. Start Visual Studio and create a new **ASP.NET Web Application (.NET Framework)** project.
2. In the **New ASP.NET Web Application** dialog box, select the **Empty** project template. Under **Add folders and core references for**, select the **Web API** checkbox.

3. Add a Web API controller named `TestController` with the following code:

```
using System.Net.Http;
using System.Web.Http;

namespace WebService.Controllers
{
    public class TestController : ApiController
    {
        public HttpResponseMessage Get()
        {
            return new HttpResponseMessage()
            {
                Content = new StringContent("GET: Test message")
            };
        }

        public HttpResponseMessage Post()
        {
            return new HttpResponseMessage()
            {
                Content = new StringContent("POST: Test message")
            };
        }

        public HttpResponseMessage Put()
        {
            return new HttpResponseMessage()
            {
                Content = new StringContent("PUT: Test message")
            };
        }
    }
}
```

4. You can run the application locally or deploy to Azure. (For the screenshots in this tutorial, the app deploys to Azure App Service Web Apps.) To verify that the web API is working, navigate to `http://hostname/api/test/`, where *hostname* is the domain where you deployed the application. You should see the response text, "GET: Test Message".

Create the WebClient project

1. Create another **ASP.NET Web Application (.NET Framework)** project and select the **MVC** project template. Optionally, select **Change Authentication** > **No Authentication**. You don't need authentication for this tutorial.

2. In **Solution Explorer**, open the file *Views/Home/Index.cshtml*. Replace the code in this file with the following:

```
<div>
    <select id="method">
        <option value="get">GET</option>
        <option value="post">POST</option>
        <option value="put">PUT</option>
    </select>
    <input type="button" value="Try it" onclick="sendRequest()" />
    <span id='value1'>(Result)</span>
</div>

@section scripts {
<script>
    // TODO: Replace with the URL of your WebService app
    var serviceUrl = 'http://mywebservice/api/test';

    function sendRequest() {
        var method = $('#method').val();

        $.ajax({
            type: method,
            url: serviceUrl
        }).done(function (data) {
            $('#value1').text(data);
        }).fail(function (jqXHR, textStatus, errorThrown) {
            $('#value1').text(jqXHR.responseText || textStatus);
        });
    }
</script>
}
```

For the *serviceUrl* variable, use the URI of the WebService app.

3. Run the WebClient app locally or publish it to another website.

When you click the "Try It" button, an AJAX request is submitted to the WebService app using the HTTP method listed in the dropdown box (GET, POST, or PUT). This lets you examine different cross-origin requests. Currently,

the WebService app does not support CORS, so if you click the button you'll get an error.

> **NOTE**
>
> If you watch the HTTP traffic in a tool like Fiddler, you'll see that the browser does send the GET request, and the request succeeds, but the AJAX call returns an error. It's important to understand that same-origin policy does not prevent the browser from *sending* the request. Instead, it prevents the application from seeing the *response*.

Enable CORS

Now let's enable CORS in the WebService app. First, add the CORS NuGet package. In Visual Studio, from the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, type the following command:

```
Install-Package Microsoft.AspNet.WebApi.Cors
```

This command installs the latest package and updates all dependencies, including the core Web API libraries. Use the `-Version` flag to target a specific version. The CORS package requires Web API 2.0 or later.

Open the file *App_Start/WebApiConfig.cs*. Add the following code to the **WebApiConfig.Register** method:

```
using System.Web.Http;
namespace WebService
{
    public static class WebApiConfig
    {
        public static void Register(HttpConfiguration config)
        {
            // New code
            config.EnableCors();

            config.Routes.MapHttpRoute(
                name: "DefaultApi",
                routeTemplate: "api/{controller}/{id}",
                defaults: new { id = RouteParameter.Optional }
            );
        }
    }
}
```

Next, add the **[EnableCors]** attribute to the `TestController` class:

```
using System.Net.Http;
using System.Web.Http;
using System.Web.Http.Cors;

namespace WebService.Controllers
{
    [EnableCors(origins: "http://mywebclient.azurewebsites.net", headers: "*", methods: "*")]
    public class TestController : ApiController
    {
        // Controller methods not shown...
    }
}
```

For the *origins* parameter, use the URI where you deployed the WebClient application. This allows cross-origin requests from WebClient, while still disallowing all other cross-domain requests. Later, I'll describe the parameters for **[EnableCors]** in more detail.

Do not include a forward slash at the end of the *origins* URL.

Redeploy the updated WebService application. You don't need to update WebClient. Now the AJAX request from WebClient should succeed. The GET, PUT, and POST methods are all allowed.

How CORS Works

This section describes what happens in a CORS request, at the level of the HTTP messages. It's important to understand how CORS works, so that you can configure the **[EnableCors]** attribute correctly and troubleshoot if things don't work as you expect.

The CORS specification introduces several new HTTP headers that enable cross-origin requests. If a browser supports CORS, it sets these headers automatically for cross-origin requests; you don't need to do anything special in your JavaScript code.

Here is an example of a cross-origin request. The "Origin" header gives the domain of the site that is making the request.

```
GET http://myservice.azurewebsites.net/api/test HTTP/1.1
Referer: http://myclient.azurewebsites.net/
Accept: */*
Accept-Language: en-US
Origin: http://myclient.azurewebsites.net
Accept-Encoding: gzip, deflate
User-Agent: Mozilla/5.0 (compatible; MSIE 10.0; Windows NT 6.2; WOW64; Trident/6.0)
Host: myservice.azurewebsites.net
```

If the server allows the request, it sets the Access-Control-Allow-Origin header. The value of this header either matches the Origin header, or is the wildcard value "*", meaning that any origin is allowed.

```
HTTP/1.1 200 OK
Cache-Control: no-cache
Pragma: no-cache
Content-Type: text/plain; charset=utf-8
Access-Control-Allow-Origin: http://myclient.azurewebsites.net
Date: Wed, 05 Jun 2013 06:27:30 GMT
Content-Length: 17

GET: Test message
```

If the response does not include the Access-Control-Allow-Origin header, the AJAX request fails. Specifically, the browser disallows the request. Even if the server returns a successful response, the browser does not make the response available to the client application.

Preflight Requests

For some CORS requests, the browser sends an additional request, called a "preflight request", before it sends the actual request for the resource.

The browser can skip the preflight request if the following conditions are true:

- The request method is GET, HEAD, or POST, *and*
- The application does not set any request headers other than Accept, Accept-Language, Content-Language, Content-Type, or Last-Event-ID, *and*
- The Content-Type header (if set) is one of the following:
  - application/x-www-form-urlencoded
  - multipart/form-data
  - text/plain

The rule about request headers applies to headers that the application sets by calling **setRequestHeader** on the **XMLHttpRequest** object. (The CORS specification calls these "author request headers".) The rule does not apply to headers the *browser* can set, such as User-Agent, Host, or Content-Length.

Here is an example of a preflight request:

```
OPTIONS http://myservice.azurewebsites.net/api/test HTTP/1.1
Accept: */*
Origin: http://myclient.azurewebsites.net
Access-Control-Request-Method: PUT
Access-Control-Request-Headers: accept, x-my-custom-header
Accept-Encoding: gzip, deflate
User-Agent: Mozilla/5.0 (compatible; MSIE 10.0; Windows NT 6.2; WOW64; Trident/6.0)
Host: myservice.azurewebsites.net
Content-Length: 0
```

The pre-flight request uses the HTTP OPTIONS method. It includes two special headers:

- Access-Control-Request-Method: The HTTP method that will be used for the actual request.
- Access-Control-Request-Headers: A list of request headers that the *application* set on the actual request. (Again, this does not include headers that the browser sets.)

Here is an example response, assuming that the server allows the request:

```
HTTP/1.1 200 OK
Cache-Control: no-cache
Pragma: no-cache
Content-Length: 0
Access-Control-Allow-Origin: http://myclient.azurewebsites.net
Access-Control-Allow-Headers: x-my-custom-header
Access-Control-Allow-Methods: PUT
Date: Wed, 05 Jun 2013 06:33:22 GMT
```

The response includes an Access-Control-Allow-Methods header that lists the allowed methods, and optionally an Access-Control-Allow-Headers header, which lists the allowed headers. If the preflight request succeeds, the browser sends the actual request, as described earlier.

Tools commonly used to test endpoints with preflight OPTIONS requests (for example, Fiddler and Postman) don't send the required OPTIONS headers by default. Confirm that the `Access-Control-Request-Method` and `Access-Control-Request-Headers` headers are sent with the request and that OPTIONS headers reach the app through IIS.

To configure IIS to allow an ASP.NET app to receive and handle OPTION requests, add the following configuration to the app's *web.config* file in the `<system.webServer><handlers>` section:

```
<system.webServer>
  <handlers>
    <remove name="ExtensionlessUrlHandler-Integrated-4.0" />
    <remove name="OPTIONSVerbHandler" />
    <add name="ExtensionlessUrlHandler-Integrated-4.0" path="*." verb="*"
type="System.Web.Handlers.TransferRequestHandler" preCondition="integratedMode,runtimeVersionv4.0" />
  </handlers>
</system.webServer>
```

The removal of `OPTIONSVerbHandler` prevents IIS from handling OPTIONS requests. The replacement of `ExtensionlessUrlHandler-Integrated-4.0` allows OPTIONS requests to reach the app because the default module registration only allows GET, HEAD, POST, and DEBUG requests with extensionless URLs.

Scope Rules for [EnableCors]

You can enable CORS per action, per controller, or globally for all Web API controllers in your application.

Per Action

To enable CORS for a single action, set the **[EnableCors]** attribute on the action method. The following example enables CORS for the `GetItem` method only.

```
public class ItemsController : ApiController
{
    public HttpResponseMessage GetAll() { ... }

    [EnableCors(origins: "http://www.example.com", headers: "*", methods: "*")]
    public HttpResponseMessage GetItem(int id) { ... }

    public HttpResponseMessage Post() { ... }
    public HttpResponseMessage PutItem(int id) { ... }
}
```

Per Controller

If you set **[EnableCors]** on the controller class, it applies to all the actions on the controller. To disable CORS for an action, add the **[DisableCors]** attribute to the action. The following example enables CORS for every method except `PutItem`.

```
[EnableCors(origins: "http://www.example.com", headers: "*", methods: "*")]
public class ItemsController : ApiController
{
    public HttpResponseMessage GetAll() { ... }
    public HttpResponseMessage GetItem(int id) { ... }
    public HttpResponseMessage Post() { ... }

    [DisableCors]
    public HttpResponseMessage PutItem(int id) { ... }
}
```

Globally

To enable CORS for all Web API controllers in your application, pass an **EnableCorsAttribute** instance to the **EnableCors** method:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        var cors = new EnableCorsAttribute("www.example.com", "*", "*");
        config.EnableCors(cors);
        // ...
    }
}
```

If you set the attribute at more than one scope, the order of precedence is:

1. Action
2. Controller
3. Global

Set the allowed origins

The *origins* parameter of the **[EnableCors]** attribute specifies which origins are allowed to access the resource. The value is a comma-separated list of the allowed origins.

```
[EnableCors(origins: "http://www.contoso.com,http://www.example.com",
    headers: "*", methods: "*")]
```

You can also use the wildcard value "*" to allow requests from any origins.

Consider carefully before allowing requests from any origin. It means that literally any website can make AJAX calls to your web API.

```
// Allow CORS for all origins. (Caution!)
[EnableCors(origins: "*", headers: "*", methods: "*")]
```

Set the allowed HTTP methods

The *methods* parameter of the **[EnableCors]** attribute specifies which HTTP methods are allowed to access the resource. To allow all methods, use the wildcard value "*". The following example allows only GET and POST requests.

```
[EnableCors(origins: "http://www.example.com", headers: "*", methods: "get,post")]
public class TestController : ApiController
{
    public HttpResponseMessage Get() { ... }
    public HttpResponseMessage Post() { ... }
    public HttpResponseMessage Put() { ... }
}
```

Set the allowed request headers

This article described earlier how a preflight request might include an Access-Control-Request-Headers header, listing the HTTP headers set by the application (the so-called "author request headers"). The *headers* parameter of the **[EnableCors]** attribute specifies which author request headers are allowed. To allow any headers, set *headers* to "*". To whitelist specific headers, set *headers* to a comma-separated list of the allowed headers:

```
[EnableCors(origins: "http://example.com",
    headers: "accept,content-type,origin,x-my-header", methods: "*")]
```

However, browsers are not entirely consistent in how they set Access-Control-Request-Headers. For example, Chrome currently includes "origin". FireFox does not include standard headers such as "Accept", even when the application sets them in script.

If you set *headers* to anything other than "*", you should include at least "accept", "content-type", and "origin", plus any custom headers that you want to support.

Set the allowed response headers

By default, the browser does not expose all of the response headers to the application. The response headers that are available by default are:

- Cache-Control
- Content-Language
- Content-Type
- Expires
- Last-Modified

- Pragma

The CORS spec calls these simple response headers. To make other headers available to the application, set the *exposedHeaders* parameter of **[EnableCors]**.

In the following example, the controller's `Get` method sets a custom header named 'X-Custom-Header'. By default, the browser will not expose this header in a cross-origin request. To make the header available, include 'X-Custom-Header' in *exposedHeaders*.

```
[EnableCors(origins: "*", headers: "*", methods: "*", exposedHeaders: "X-Custom-Header")]
public class TestController : ApiController
{
    public HttpResponseMessage Get()
    {
        var resp = new HttpResponseMessage()
        {
            Content = new StringContent("GET: Test message")
        };
        resp.Headers.Add("X-Custom-Header", "hello");
        return resp;
    }
}
```

Pass credentials in cross-origin requests

Credentials require special handling in a CORS request. By default, the browser does not send any credentials with a cross-origin request. Credentials include cookies as well as HTTP authentication schemes. To send credentials with a cross-origin request, the client must set **XMLHttpRequest.withCredentials** to true.

Using **XMLHttpRequest** directly:

```
var xhr = new XMLHttpRequest();
xhr.open('get', 'http://www.example.com/api/test');
xhr.withCredentials = true;
```

In jQuery:

```
$.ajax({
    type: 'get',
    url: 'http://www.example.com/api/test',
    xhrFields: {
        withCredentials: true
    }
```

In addition, the server must allow the credentials. To allow cross-origin credentials in Web API, set the **SupportsCredentials** property to true on the **[EnableCors]** attribute:

```
[EnableCors(origins: "http://myclient.azurewebsites.net", headers: "*",
    methods: "*", SupportsCredentials = true)]
```

If this property is true, the HTTP response will include an Access-Control-Allow-Credentials header. This header tells the browser that the server allows credentials for a cross-origin request.

If the browser sends credentials, but the response does not include a valid Access-Control-Allow-Credentials header, the browser will not expose the response to the application, and the AJAX request fails.

Be careful about setting **SupportsCredentials** to true, because it means a website at another domain can send a

logged-in user's credentials to your Web API on the user's behalf, without the user being aware. The CORS spec also states that setting *origins* to "*" is invalid if **SupportsCredentials** is true.

Custom CORS policy providers

The **[EnableCors]** attribute implements the **ICorsPolicyProvider** interface. You can provide your own implementation by creating a class that derives from **Attribute** and implements **ICorsPolicyProvider**.

```
[AttributeUsage(AttributeTargets.Method | AttributeTargets.Class, AllowMultiple = false)]
public class MyCorsPolicyAttribute : Attribute, ICorsPolicyProvider
{
    private CorsPolicy _policy;

    public MyCorsPolicyAttribute()
    {
        // Create a CORS policy.
        _policy = new CorsPolicy
        {
            AllowAnyMethod = true,
            AllowAnyHeader = true
        };

        // Add allowed origins.
        _policy.Origins.Add("http://myclient.azurewebsites.net");
        _policy.Origins.Add("http://www.contoso.com");
    }

    public Task<CorsPolicy> GetCorsPolicyAsync(HttpRequestMessage request)
    {
        return Task.FromResult(_policy);
    }
}
```

Now you can apply the attribute any place that you would put **[EnableCors]**.

```
[MyCorsPolicy]
public class TestController : ApiController
{
    .. //
```

For example, a custom CORS policy provider could read the settings from a configuration file.

As an alternative to using attributes, you can register an **ICorsPolicyProviderFactory** object that creates **ICorsPolicyProvider** objects.

```
public class CorsPolicyFactory : ICorsPolicyProviderFactory
{
    ICorsPolicyProvider _provider = new MyCorsPolicyProvider();

    public ICorsPolicyProvider GetCorsPolicyProvider(HttpRequestMessage request)
    {
        return _provider;
    }
}
```

To set the **ICorsPolicyProviderFactory**, call the **SetCorsPolicyProviderFactory** extension method at startup, as follows:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.SetCorsPolicyProviderFactory(new CorsPolicyFactory());
        config.EnableCors();

        // ...
    }
}
```

Browser support

The Web API CORS package is a server-side technology. The user's browser also needs to support CORS. Fortunately, the current versions of all major browsers include support for CORS.

Authentication Filters in ASP.NET Web API 2

2/20/2020 • 8 minutes to read • Edit Online

by Mike Wasson

> An authentication filter is a component that authenticates an HTTP request. Web API 2 and MVC 5 both support authentication filters, but they differ slightly, mostly in the naming conventions for the filter interface. This topic describes Web API authentication filters.

Authentication filters let you set an authentication scheme for individual controllers or actions. That way, your app can support different authentication mechanisms for different HTTP resources.

In this article, I'll show code from the Basic Authentication sample on https://github.com/aspnet/samples. The sample shows an authentication filter that implements the HTTP Basic Access Authentication scheme (RFC 2617). The filter is implemented in a class named `IdentityBasicAuthenticationAttribute`. I won't show all of the code from the sample, just the parts that illustrate how to write an authentication filter.

Setting an Authentication Filter

Like other filters, authentication filters can be applied per-controller, per-action, or globally to all Web API controllers.

To apply an authentication filter to a controller, decorate the controller class with the filter attribute. The following code sets the `[IdentityBasicAuthentication]` filter on a controller class, which enables Basic Authentication for all of the controller's actions.

```
[IdentityBasicAuthentication] // Enable Basic authentication for this controller.
[Authorize] // Require authenticated requests.
public class HomeController : ApiController
{
    public IHttpActionResult Get() { . . . }
    public IHttpActionResult Post() { . . . }
}
```

To apply the filter to one action, decorate the action with the filter. The following code sets the `[IdentityBasicAuthentication]` filter on the controller's `Post` method.

```
[Authorize] // Require authenticated requests.
public class HomeController : ApiController
{
    public IHttpActionResult Get() { . . . }

    [IdentityBasicAuthentication] // Enable Basic authentication for this action.
    public IHttpActionResult Post() { . . . }
}
```

To apply the filter to all Web API controllers, add it to **GlobalConfiguration.Filters**.

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.Filters.Add(new IdentityBasicAuthenticationAttribute());

        // Other configuration code not shown...
    }
}
```

Implementing a Web API Authentication Filter

In Web API, authentication filters implement the System.Web.Http.Filters.IAuthenticationFilter interface. They should also inherit from **System.Attribute**, in order to be applied as attributes.

The **IAuthenticationFilter** interface has two methods:

- **AuthenticateAsync** authenticates the request by validating credentials in the request, if present.
- **ChallengeAsync** adds an authentication challenge to the HTTP response, if needed.

These methods correspond to the authentication flow defined in RFC 2612 and RFC 2617:

1. The client sends credentials in the Authorization header. This typically happens after the client receives a 401 (Unauthorized) response from the server. However, a client can send credentials with any request, not just after getting a 401.
2. If the server does not accept the credentials, it returns a 401 (Unauthorized) response. The response includes a Www-Authenticate header that contains one or more challenges. Each challenge specifies an authentication scheme recognized by the server.

The server can also return 401 from an anonymous request. In fact, that's typically how the authentication process is initiated:

1. The client sends an anonymous request.
2. The server returns 401.
3. The clients resends the request with credentials.

This flow includes both *authentication* and *authorization* steps.

- Authentication proves the identity of the client.
- Authorization determines whether the client can access a particular resource.

In Web API, authentication filters handle authentication, but not authorization. Authorization should be done by an authorization filter or inside the controller action.

Here is the flow in the Web API 2 pipeline:

1. Before invoking an action, Web API creates a list of the authentication filters for that action. This includes filters with action scope, controller scope, and global scope.
2. Web API calls **AuthenticateAsync** on every filter in the list. Each filter can validate credentials in the request. If any filter successfully validates credentials, the filter creates an **IPrincipal** and attaches it to the request. A filter can also trigger an error at this point. If so, the rest of the pipeline does not run.
3. Assuming there is no error, the request flows through the rest of the pipeline.
4. Finally, Web API calls every authentication filter's **ChallengeAsync** method. Filters use this method to add a challenge to the response, if needed. Typically (but not always) that would happen in response to a 401 error.

The following diagrams show two possible cases. In the first, the authentication filter successfully authenticates the request, an authorization filter authorizes the request, and the controller action returns 200 (OK).

In the second example, the authentication filter authenticates the request, but the authorization filter returns 401 (Unauthorized). In this case, the controller action is not invoked. The authentication filter adds a Www-Authenticate header to the response.

Other combinations are possible—for example, if the controller action allows anonymous requests, you might have an authentication filter but no authorization.

Implementing the AuthenticateAsync Method

The **AuthenticateAsync** method tries to authenticate the request. Here is the method signature:

```
Task AuthenticateAsync(
    HttpAuthenticationContext context,
    CancellationToken cancellationToken
)
```

The **AuthenticateAsync** method must do one of the following:

1. Nothing (no-op).
2. Create an **IPrincipal** and set it on the request.
3. Set an error result.

Option (1) means the request did not have any credentials that the filter understands. Option (2) means the filter successfully authenticated the request. Option (3) means the request had invalid credentials (like the wrong password), which triggers an error response.

Here is a general outline for implementing **AuthenticateAsync**.

1. Look for credentials in the request.
2. If there are no credentials, do nothing and return (no-op).
3. If there are credentials but the filter does not recognize the authentication scheme, do nothing and return (no-op). Another filter in the pipeline might understand the scheme.
4. If there are credentials that the filter understands, try to authenticate them.
5. If the credentials are bad, return 401 by setting `context.ErrorResult`.
6. If the credentials are valid, create an **IPrincipal** and set `context.Principal`.

The follow code shows the **AuthenticateAsync** method from the Basic Authentication sample. The comments indicate each step. The code shows several types of error: An Authorization header with no credentials, malformed credentials, and bad username/password.

```
public async Task AuthenticateAsync(HttpAuthenticationContext context, CancellationToken cancellationToken)
{
    // 1. Look for credentials in the request.
    HttpRequestMessage request = context.Request;
    AuthenticationHeaderValue authorization = request.Headers.Authorization;

    // 2. If there are no credentials, do nothing.
    if (authorization == null)
    {
        return;
    }

    // 3. If there are credentials but the filter does not recognize the
    //    authentication scheme, do nothing.
    if (authorization.Scheme != "Basic")
    {
        return;
    }

    // 4. If there are credentials that the filter understands, try to validate them.
    // 5. If the credentials are bad, set the error result.
    if (String.IsNullOrEmpty(authorization.Parameter))
    {
        context.ErrorResult = new AuthenticationFailureResult("Missing credentials", request);
        return;
    }

    Tuple<string, string> userNameAndPassword = ExtractUserNameAndPassword(authorization.Parameter);
    if (userNameAndPassword == null)
    {
        context.ErrorResult = new AuthenticationFailureResult("Invalid credentials", request);
    }

    string userName = userNameAndPassword.Item1;
    string password = userNameAndPassword.Item2;

    IPrincipal principal = await AuthenticateAsync(userName, password, cancellationToken);
    if (principal == null)
    {
        context.ErrorResult = new AuthenticationFailureResult("Invalid username or password", request);
    }

    // 6. If the credentials are valid, set principal.
    else
    {
        context.Principal = principal;
    }

}
```

Setting an Error Result

If the credentials are invalid, the filter must set `context.ErrorResult` to an **IHttpActionResult** that creates an error response. For more information about **IHttpActionResult**, see Action Results in Web API 2.

The Basic Authentication sample includes an `AuthenticationFailureResult` class that is suitable for this purpose.

```
public class AuthenticationFailureResult : IHttpActionResult
{
    public AuthenticationFailureResult(string reasonPhrase, HttpRequestMessage request)
    {
        ReasonPhrase = reasonPhrase;
        Request = request;
    }

    public string ReasonPhrase { get; private set; }

    public HttpRequestMessage Request { get; private set; }

    public Task<HttpResponseMessage> ExecuteAsync(CancellationToken cancellationToken)
    {
        return Task.FromResult(Execute());
    }

    private HttpResponseMessage Execute()
    {
        HttpResponseMessage response = new HttpResponseMessage(HttpStatusCode.Unauthorized);
        response.RequestMessage = Request;
        response.ReasonPhrase = ReasonPhrase;
        return response;
    }
}
```

Implementing ChallengeAsync

The purpose of the **ChallengeAsync** method is to add authentication challenges to the response, if needed. Here is the method signature:

```
Task ChallengeAsync(
    HttpAuthenticationChallengeContext context,
    CancellationToken cancellationToken
)
```

The method is called on every authentication filter in the request pipeline.

It's important to understand that **ChallengeAsync** is called *before* the HTTP response is created, and possibly even before the controller action runs. When **ChallengeAsync** is called, `context.Result` contains an **IHttpActionResult**, which is used later to create the HTTP response. So when **ChallengeAsync** is called, you don't know anything about the HTTP response yet. The **ChallengeAsync** method should replace the original value of `context.Result` with a new **IHttpActionResult**. This **IHttpActionResult** must wrap the original `context.Result`.

I'll call the original **IHttpActionResult** the *inner result*, and the new **IHttpActionResult** the *outer result*. The outer result must do the following:

1. Invoke the inner result to create the HTTP response.
2. Examine the response.
3. Add an authentication challenge to the response, if needed.

The following example is taken from the Basic Authentication sample. It defines an **IHttpActionResult** for the outer result.

```
public class AddChallengeOnUnauthorizedResult : IHttpActionResult
{
    public AddChallengeOnUnauthorizedResult(AuthenticationHeaderValue challenge, IHttpActionResult
innerResult)
    {
        Challenge = challenge;
        InnerResult = innerResult;
    }

    public AuthenticationHeaderValue Challenge { get; private set; }

    public IHttpActionResult InnerResult { get; private set; }

    public async Task<HttpResponseMessage> ExecuteAsync(CancellationToken cancellationToken)
    {
        HttpResponseMessage response = await InnerResult.ExecuteAsync(cancellationToken);

        if (response.StatusCode == HttpStatusCode.Unauthorized)
        {
            // Only add one challenge per authentication scheme.
            if (!response.Headers.WwwAuthenticate.Any((h) => h.Scheme == Challenge.Scheme))
            {
                response.Headers.WwwAuthenticate.Add(Challenge);
            }
        }

        return response;
    }
}
```

The `InnerResult` property holds the inner **IHttpActionResult**. The `Challenge` property represents a Www-Authentication header. Notice that **ExecuteAsync** first calls `InnerResult.ExecuteAsync` to create the HTTP response, and then adds the challenge if needed.

Check the response code before adding the challenge. Most authentication schemes only add a challenge if the response is 401, as shown here. However, some authentication schemes do add a challenge to a success response. For example, see Negotiate (RFC 4559).

Given the `AddChallengeOnUnauthorizedResult` class, the actual code in **ChallengeAsync** is simple. You just create the result and attach it to `context.Result`.

```
public Task ChallengeAsync(HttpAuthenticationChallengeContext context, CancellationToken cancellationToken)
{
    var challenge = new AuthenticationHeaderValue("Basic");
    context.Result = new AddChallengeOnUnauthorizedResult(challenge, context.Result);
    return Task.FromResult(0);
}
```

Note: The Basic Authentication sample abstracts this logic a bit, by placing it in an extension method.

Combining Authentication Filters with Host-Level Authentication

"Host-level authentication" is authentication performed by the host (such as IIS), before the request reaches the

Web API framework.

Often, you may want to enable host-level authentication for the rest of your application, but disable it for your Web API controllers. For example, a typical scenario is to enable Forms Authentication at the host level, but use token-based authentication for Web API.

To disable host-level authentication inside the Web API pipeline, call `config.SuppressHostPrincipal()` in your configuration. This causes Web API to remove the **IPrincipal** from any request that enters the Web API pipeline. Effectively, it "un-authenticates" the request.

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.SuppressHostPrincipal();

        // Other configuration code not shown...
    }
}
```

Basic Authentication in ASP.NET Web API

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson

Basic authentication is defined in RFC 2617, HTTP Authentication: Basic and Digest Access Authentication.

Disadvantages

- User credentials are sent in the request.
- Credentials are sent as plaintext.
- Credentials are sent with every request.
- No way to log out, except by ending the browser session.
- Vulnerable to cross-site request forgery (CSRF); requires anti-CSRF measures.

Advantages

- Internet standard.
- Supported by all major browsers.
- Relatively simple protocol.

Basic authentication works as follows:

1. If a request requires authentication, the server returns 401 (Unauthorized). The response includes a WWW-Authenticate header, indicating the server supports Basic authentication.
2. The client sends another request, with the client credentials in the Authorization header. The credentials are formatted as the string "name:password", base64-encoded. The credentials are not encrypted.

Basic authentication is performed within the context of a "realm." The server includes the name of the realm in the WWW-Authenticate header. The user's credentials are valid within that realm. The exact scope of a realm is defined by the server. For example, you might define several realms in order to partition resources.

Because the credentials are sent unencrypted, Basic authentication is only secure over HTTPS. See Working with SSL in Web API.

Basic authentication is also vulnerable to CSRF attacks. After the user enters credentials, the browser automatically sends them on subsequent requests to the same domain, for the duration of the session. This includes AJAX requests. See Preventing Cross-Site Request Forgery (CSRF) Attacks.

Basic Authentication with IIS

IIS supports Basic authentication, but there is a caveat: The user is authenticated against their Windows credentials.

That means the user must have an account on the server's domain. For a public-facing web site, you typically want to authenticate against an ASP.NET membership provider.

To enable Basic authentication using IIS, set the authentication mode to "Windows" in the Web.config of your ASP.NET project:

```
<system.web>
    <authentication mode="Windows" />
</system.web>
```

In this mode, IIS uses Windows credentials to authenticate. In addition, you must enable Basic authentication in IIS. In IIS Manager, go to Features View, select Authentication, and enable Basic authentication.

In your Web API project, add the `[Authorize]` attribute for any controller actions that need authentication.

A client authenticates itself by setting the Authorization header in the request. Browser clients perform this step automatically. Nonbrowser clients will need to set the header.

Basic Authentication with Custom Membership

As mentioned, the Basic Authentication built into IIS uses Windows credentials. That means you need to create accounts for your users on the hosting server. But for an internet application, user accounts are typically stored in an external database.

The following code how an HTTP module that performs Basic Authentication. You can easily plug in an ASP.NET membership provider by replacing the `CheckPassword` method, which is a dummy method in this example.

In Web API 2, you should consider writing an authentication filter or OWIN middleware, instead of an HTTP module.

```
namespace WebHostBasicAuth.Modules
{
    public class BasicAuthHttpModule : IHttpModule
    {
        private const string Realm = "My Realm";

        public void Init(HttpApplication context)
        {
            // Register event handlers
            context.AuthenticateRequest += OnApplicationAuthenticateRequest;
            context.EndRequest += OnApplicationEndRequest;
        }

        private static void SetPrincipal(IPrincipal principal)
        {
            Thread.CurrentPrincipal = principal;
            if (HttpContext.Current != null)
            {
                HttpContext.Current.User = principal;
            }
        }
```

```
        // TODO: Here is where you would validate the username and password.
        private static bool CheckPassword(string username, string password)
        {
            return username == "user" && password == "password";
        }

        private static void AuthenticateUser(string credentials)
        {
            try
            {
                var encoding = Encoding.GetEncoding("iso-8859-1");
                credentials = encoding.GetString(Convert.FromBase64String(credentials));

                int separator = credentials.IndexOf(':');
                string name = credentials.Substring(0, separator);
                string password = credentials.Substring(separator + 1);

                if (CheckPassword(name, password))
                {
                    var identity = new GenericIdentity(name);
                    SetPrincipal(new GenericPrincipal(identity, null));
                }
                else
                {
                    // Invalid username or password.
                    HttpContext.Current.Response.StatusCode = 401;
                }
            }
            catch (FormatException)
            {
                // Credentials were not formatted correctly.
                HttpContext.Current.Response.StatusCode = 401;
            }
        }

        private static void OnApplicationAuthenticateRequest(object sender, EventArgs e)
        {
            var request = HttpContext.Current.Request;
            var authHeader = request.Headers["Authorization"];
            if (authHeader != null)
            {
                var authHeaderVal = AuthenticationHeaderValue.Parse(authHeader);

                // RFC 2617 sec 1.2, "scheme" name is case-insensitive
                if (authHeaderVal.Scheme.Equals("basic",
                        StringComparison.OrdinalIgnoreCase) &&
                    authHeaderVal.Parameter != null)
                {
                    AuthenticateUser(authHeaderVal.Parameter);
                }
            }
        }

        // If the request was unauthorized, add the WWW-Authenticate header
        // to the response.
        private static void OnApplicationEndRequest(object sender, EventArgs e)
        {
            var response = HttpContext.Current.Response;
            if (response.StatusCode == 401)
            {
                response.Headers.Add("WWW-Authenticate",
                    string.Format("Basic realm=\"{0}\"", Realm));
            }
        }

        public void Dispose()
        {
        }
```

```
    }
}
```

To enable the HTTP module, add the following to your web.config file in the **system.webServer** section:

```
<system.webServer>
    <modules>
      <add name="BasicAuthHttpModule"
        type="WebHostBasicAuth.Modules.BasicAuthHttpModule, YourAssemblyName"/>
    </modules>
```

Replace "YourAssemblyName" with the name of the assembly (not including the "dll" extension).

You should disable other authentication schemes, such as Forms or Windows auth.

Forms Authentication in ASP.NET Web API

2/20/2020 • 2 minutes to read • Edit Online

by Mike Wasson

Forms authentication uses an HTML form to send the user's credentials to the server. It is not an Internet standard. Forms authentication is only appropriate for web APIs that are called from a web application, so that the user can interact with the HTML form.

ADVANTAGES	DISADVANTAGES
- Easy to implement: Built into ASP.NET. - Uses ASP.NET membership provider, which makes it easy to manage user accounts.	- Not a standard HTTP authentication mechanism; uses HTTP cookies instead of the standard Authorization header. - Requires a browser client. - Credentials are sent as plaintext. - Vulnerable to cross-site request forgery (CSRF); requires anti-CSRF measures. - Difficult to use from nonbrowser clients. Login requires a browser. - User credentials are sent in the request. - Some users disable cookies.

Briefly, forms authentication in ASP.NET works like this:

1. The client requests a resource that requires authentication.
2. If the user is not authenticated, the server returns HTTP 302 (Found) and redirects to a login page.
3. The user enters credentials and submits the form.
4. The server returns another HTTP 302 that redirects back to the original URI. This response includes an authentication cookie.
5. The client requests the resource again. The request includes the authentication cookie, so the server grants the request.

For more information, see An Overview of Forms Authentication.

Using Forms Authentication with Web API

To create an application that uses forms authentication, select the "Internet Application" template in the MVC 4 project wizard. This template creates MVC controllers for account management. You can also use the "Single Page

Application" template, available in the ASP.NET Fall 2012 Update.

In your web API controllers, you can restrict access by using the `[Authorize]` attribute, as described in Using the [Authorize] Attribute.

Forms-authentication uses a session cookie to authenticate requests. Browsers automatically send all relevant cookies to the destination web site. This feature makes forms authentication potentially vulnerable to cross-site request forgery (CSRF) attacks See Preventing Cross-Site Request Forgery (CSRF) Attacks.

Forms authentication does not encrypt the user's credentials. Therefore, forms authentication is not secure unless used with SSL. See Working with SSL in Web API.

Integrated Windows Authentication

9/16/2020 • 2 minutes to read • Edit Online

by Mike Wasson

Integrated Windows authentication enables users to log in with their Windows credentials, using Kerberos or NTLM. The client sends credentials in the Authorization header. Windows authentication is best suited for an intranet environment. For more information, see Windows Authentication.

ADVANTAGES	DISADVANTAGES
Built into IIS.	Not recommended for Internet applications.
Does not send the user credentials in the request.	Requires Kerberos or NTLM support in the client.
If the client computer belongs to the domain (for example, intranet application), the user does not need to enter credentials.	Client must be in the Active Directory domain.

NOTE

If your application is hosted on Azure and you have an on-premise Active Directory domain, consider federating your on-premise AD with Azure Active Directory. That way, users can log in with their on-premise credentials, but the authentication is performed by Azure AD. For more information, see Azure Authentication.

To create an application that uses Integrated Windows authentication, select the "Intranet Application" template in the MVC 4 project wizard. This project template puts the following setting in the Web.config file:

```
<system.web>
    <authentication mode="Windows" />
</system.web>
```

On the client side, Integrated Windows authentication works with any browser that supports the Negotiate authentication scheme, which includes most major browsers. For .NET client applications, the **HttpClient** class supports Windows authentication:

```
HttpClientHandler handler = new HttpClientHandler()
{
    UseDefaultCredentials = true
};

HttpClient client = new HttpClient(handler);
```

Windows authentication is vulnerable to cross-site request forgery (CSRF) attacks. See Preventing Cross-Site Request Forgery (CSRF) Attacks.

Working with SSL in Web API

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson

Several common authentication schemes are not secure over plain HTTP. In particular, Basic authentication and forms authentication send unencrypted credentials. To be secure, these authentication schemes *must* use SSL. In addition, SSL client certificates can be used to authenticate clients.

Enabling SSL on the Server

To set up SSL in IIS 7 or later:

- Create or get a certificate. For testing, you can create a self-signed certificate.
- Add an HTTPS binding.

For details, see How to Set Up SSL on IIS 7.

For local testing, you can enable SSL in IIS Express from Visual Studio. In the Properties window, set **SSL Enabled** to **True**. Note the value of **SSL URL**; use this URL for testing HTTPS connections.

Enforcing SSL in a Web API Controller

If you have both an HTTPS and an HTTP binding, clients can still use HTTP to access the site. You might allow some resources to be available through HTTP, while other resources require SSL. In that case, use an action filter to require SSL for the protected resources. The following code shows a Web API authentication filter that checks for SSL:

```
public class RequireHttpsAttribute : AuthorizationFilterAttribute
{
    public override void OnAuthorization(HttpActionContext actionContext)
    {
        if (actionContext.Request.RequestUri.Scheme != Uri.UriSchemeHttps)
        {
            actionContext.Response = new HttpResponseMessage(System.Net.HttpStatusCode.Forbidden)
            {
                ReasonPhrase = "HTTPS Required"
            };
        }
        else
        {
            base.OnAuthorization(actionContext);
        }
    }
}
```

Add this filter to any Web API actions that require SSL:

```
public class ValuesController : ApiController
{
    [RequireHttps]
    public HttpResponseMessage Get() { ... }
}
```

SSL Client Certificates

SSL provides authentication by using Public Key Infrastructure certificates. The server must provide a certificate that authenticates the server to the client. It is less common for the client to provide a certificate to the server, but this is one option for authenticating clients. To use client certificates with SSL, you need a way to distribute signed certificates to your users. For many application types, this will not be a good user experience, but in some environments (for example, enterprise) it may be feasible.

ADVANTAGES	DISADVANTAGES
- Certificate credentials are stronger than username/password. - SSL provides a complete secure channel, with authentication, message integrity, and message encryption.	- You must obtain and manage PKI certificates. - The client platform must support SSL client certificates.

To configure IIS to accept client certificates, open IIS Manager and perform the following steps:

1. Click the site node in the tree view.
2. Double-click the **SSL Settings** feature in the middle pane.
3. Under **Client Certificates**, select one of these options:
   - **Accept**: IIS will accept a certificate from the client, but does not require one.
   - **Require**: Require a client certificate. (To enable this option, you must also select "Require SSL")

You can also set these options in the ApplicationHost.config file:

```
<system.webServer>
    <security>
        <access sslFlags="Ssl, SslNegotiateCert" />
        <!-- To require a client cert: -->
        <!-- <access sslFlags="Ssl, SslRequireCert" /> -->
    </security>
</system.webServer>
```

The **SslNegotiateCert** flag means IIS will accept a certificate from the client, but does not require one (equivalent to the "Accept" option in IIS Manager). To require a certificate, set the **SslRequireCert** flag. For testing, you can also set these options in IIS Express, in the local applicationhost.Config file, located in "Documents\IISExpress\config".

Creating a Client Certificate for Testing

For testing purposes, you can use MakeCert.exe to create a client certificate. First, create a test root authority:

```
makecert.exe -n "CN=Development CA" -r -sv TempCA.pvk TempCA.cer
```

Makecert will prompt you to enter a password for the private key.

Next, add the certificate to the test server's "Trusted Root Certification Authorities" store, as follows:

1. Open MMC.
2. Under **File**, select **Add/Remove Snap-In**.
3. Select **Computer Account**.
4. Select **Local computer** and complete the wizard.
5. Under the navigation pane, expand the "Trusted Root Certification Authorities" node.
6. On the **Action** menu, point to **All Tasks**, and then click **Import** to start the Certificate Import Wizard.
7. Browse to the certificate file, TempCA.cer.
8. Click **Open**, then click **Next** and complete the wizard. (You will be prompted to re-enter the password.)

Now create a client certificate that is signed by the first certificate:

```
makecert.exe -pe -ss My -sr CurrentUser -a sha1 -sky exchange -n "CN=name"
     -eku 1.3.6.1.5.5.7.3.2 -sk SignedByCA -ic TempCA.cer -iv TempCA.pvk
```

Using Client Certificates in Web API

On the server side, you can get the client certificate by calling GetClientCertificate on the request message. The method returns null if there is no client certificate. Otherwise, it returns an **X509Certificate2** instance. Use this object to get information from the certificate, such as the issuer and subject. Then you can use this information for authentication and/or authorization.

```
X509Certificate2 cert = Request.GetClientCertificate();
string issuer = cert.Issuer;
string subject = cert.Subject;
```

ASP.NET Web API: Deployment and Hosting

2/20/2020 • 2 minutes to read • Edit Online

How to host your web API.

- Use OWIN to Self-Host Web API 2
- Host Web API 2 in an Azure Worker Role

Use OWIN to Self-Host ASP.NET Web API

2/20/2020 • 2 minutes to read • Edit Online

This tutorial shows how to host ASP.NET Web API in a console application, using OWIN to self-host the Web API framework.

Open Web Interface for .NET (OWIN) defines an abstraction between .NET web servers and web applications. OWIN decouples the web application from the server, which makes OWIN ideal for self-hosting a web application in your own process, outside of IIS.

Software versions used in the tutorial

- Visual Studio 2017
- Web API 5.2.7

NOTE

You can find the complete source code for this tutorial at github.com/aspnet/samples.

Create a console application

On the **File** menu, **New**, then select **Project**. From **Installed**, under **Visual C#**, select **Windows Desktop** and then select **Console App (.Net Framework)**. Name the project "OwinSelfhostSample" and select **OK**.

Add the Web API and OWIN packages

From the **Tools** menu, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, enter the following command:

```
Install-Package Microsoft.AspNet.WebApi.OwinSelfHost
```

This will install the WebAPI OWIN selfhost package and all the required OWIN packages.

```
Package Manager Console
Package source: nuget.org    Default project: OwinSelfHostSample
Each package is licensed to you by its owner. Microsoft is not responsible for, no
which are governed by additional licenses. Follow the package source (feed) URL to

Package Manager Console Host Version 2.7.40911.287

Type 'get-help NuGet' to see all available NuGet commands.

PM> Install-Package Microsoft.AspNet.WebApi.OwinSelfHost
```

Configure Web API for self-host

In Solution Explorer, right-click the project and select **Add** / **Class** to add a new class. Name the class `Startup`.

Replace all of the boilerplate code in this file with the following:

```
using Owin;
using System.Web.Http;

namespace OwinSelfhostSample
{
    public class Startup
    {
        // This code configures Web API. The Startup class is specified as a type
        // parameter in the WebApp.Start method.
        public void Configuration(IAppBuilder appBuilder)
        {
            // Configure Web API for self-host.
            HttpConfiguration config = new HttpConfiguration();
            config.Routes.MapHttpRoute(
                name: "DefaultApi",
                routeTemplate: "api/{controller}/{id}",
                defaults: new { id = RouteParameter.Optional }
            );

            appBuilder.UseWebApi(config);
        }
    }
}
```

Add a Web API controller

Next, add a Web API controller class. In Solution Explorer, right-click the project and select **Add** / **Class** to add a new class. Name the class `ValuesController`.

Replace all of the boilerplate code in this file with the following:

```
using System.Collections.Generic;
using System.Web.Http;

namespace OwinSelfhostSample
{
    public class ValuesController : ApiController
    {
        // GET api/values
        public IEnumerable<string> Get()
        {
            return new string[] { "value1", "value2" };
        }

        // GET api/values/5
        public string Get(int id)
        {
            return "value";
        }

        // POST api/values
        public void Post([FromBody]string value)
        {
        }

        // PUT api/values/5
        public void Put(int id, [FromBody]string value)
        {
        }

        // DELETE api/values/5
        public void Delete(int id)
        {
        }
    }
}
```

Start the OWIN Host and make a request with HttpClient

Replace all of the boilerplate code in the Program.cs file with the following:

```
using Microsoft.Owin.Hosting;
using System;
using System.Net.Http;

namespace OwinSelfhostSample
{
    public class Program
    {
        static void Main()
        {
            string baseAddress = "http://localhost:9000/";

            // Start OWIN host
            using (WebApp.Start<Startup>(url: baseAddress))
            {
                // Create HttpClient and make a request to api/values
                HttpClient client = new HttpClient();

                var response = client.GetAsync(baseAddress + "api/values").Result;

                Console.WriteLine(response);
                Console.WriteLine(response.Content.ReadAsStringAsync().Result);
                Console.ReadLine();
            }
        }
    }
 }
```

Run the application

To run the application, press F5 in Visual Studio. The output should look like the following:

```
StatusCode: 200, ReasonPhrase: 'OK', Version: 1.1, Content: System.Net.Http.StreamContent, Headers:
{
  Date: Tue, 09 Jul 2013 18:10:15 GMT
  Server: Microsoft-HTTPAPI/2.0
  Content-Length: 19
  Content-Type: application/json; charset=utf-8
}
["value1","value2"]
```

Host ASP.NET Web API in an Azure Worker Role

Host ASP.NET Web API 2 in an Azure Worker Role

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

This tutorial shows how to host ASP.NET Web API in an Azure Worker Role, using OWIN to self-host the Web API framework.

Open Web Interface for .NET (OWIN) defines an abstraction between .NET web servers and web applications. OWIN decouples the web application from the server, which makes OWIN ideal for self-hosting a web application in your own process, outside of IIS–for example, inside an Azure worker role.

In this tutorial, you'll use the Microsoft.Owin.Host.HttpListener package, which provides an HTTP server that be used to self-host OWIN applications.

Software versions used in the tutorial

- Visual Studio 2013
- Web API 2
- Azure SDK for .NET 2.3

Create a Microsoft Azure Project

Start Visual Studio with administrator privileges. Administrator privileges are needed to debug the application locally, using the Azure compute emulator.

On the **File** menu, click **New**, then click **Project**. From **Installed Templates**, under Visual C#, click **Cloud** and then click **Windows Azure Cloud Service**. Name the project "AzureApp" and click **OK**.

In the **New Windows Azure Cloud Service** dialog, double-click **Worker Role**. Leave the default name ("WorkerRole1"). This step adds a worker role to the solution. Click **OK**.

The Visual Studio solution that is created contains two projects:

- "AzureApp" defines the roles and configuration for the Azure application.
- "WorkerRole1" contains the code for the worker role.

In general, an Azure application can contain multiple roles, although this tutorial uses a single role.

Add the Web API and OWIN Packages

From the **Tools** menu, click **NuGet Package Manager**, then click **Package Manager Console**.

In the Package Manager Console window, enter the following command:

```
Install-Package Microsoft.AspNet.WebApi.OwinSelfHost
```

Add an HTTP Endpoint

In Solution Explorer, expand the AzureApp project. Expand the Roles node, right-click WorkerRole1, and select **Properties**.

Click **Endpoints**, and then click **Add Endpoint**.

In the **Protocol** dropdown list, select "http". In **Public Port** and **Private Port**, type 80. These port numbers can be different. The public port is what clients use when they send a request to the role.

Configure Web API for Self-Host

In Solution Explorer, right click the WorkerRole1 project and select **Add** / **Class** to add a new class. Name the class `Startup`.

Replace all of the boilerplate code in this file with the following:

```
using Owin;
using System.Web.Http;

namespace WorkerRole1
{
    class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            HttpConfiguration config = new HttpConfiguration();
            config.Routes.MapHttpRoute(
                "Default",
                "{controller}/{id}",
                new { id = RouteParameter.Optional });

            app.UseWebApi(config);
        }
    }
}
```

Add a Web API Controller

Next, add a Web API controller class. Right-click the WorkerRole1 project and select **Add** / **Class**. Name the class TestController. Replace all of the boilerplate code in this file with the following:

```
using System;
using System.Net.Http;
using System.Web.Http;

namespace WorkerRole1
{
    public class TestController : ApiController
    {
        public HttpResponseMessage Get()
        {
            return new HttpResponseMessage()
            {
                Content = new StringContent("Hello from OWIN!")
            };
        }

        public HttpResponseMessage Get(int id)
        {
            string msg = String.Format("Hello from OWIN (id = {0})", id);
            return new HttpResponseMessage()
            {
                Content = new StringContent(msg)
            };
        }
    }
}
```

For simplicity, this controller just defines two GET methods that return plain text.

Start the OWIN Host

Open the WorkerRole.cs file. This class defines the code that runs when the worker role is started and stopped.

Add the following using statement:

```
using Microsoft.Owin.Hosting;
```

Add an **IDisposable** member to the `WorkerRole` class:

```
public class WorkerRole : RoleEntryPoint
{
    private IDisposable _app = null;

    // ....
}
```

In the `OnStart` method, add the following code to start the host:

```
public override bool OnStart()
{
    ServicePointManager.DefaultConnectionLimit = 12;

    // New code:
    var endpoint = RoleEnvironment.CurrentRoleInstance.InstanceEndpoints["Endpoint1"];
    string baseUri = String.Format("{0}://{1}",
        endpoint.Protocol, endpoint.IPEndpoint);

    Trace.TraceInformation(String.Format("Starting OWIN at {0}", baseUri),
        "Information");

    _app = WebApp.Start<Startup>(new StartOptions(url: baseUri));
    return base.OnStart();
}
```

The **WebApp.Start** method starts the OWIN host. The name of the `Startup` class is a type parameter to the method. By convention, the host will call the `Configure` method of this class.

Override the `OnStop` to dispose of the *_app* instance:

```
public override void OnStop()
{
    if (_app != null)
    {
        _app.Dispose();
    }
    base.OnStop();
}
```

Here is the complete code for WorkerRole.cs:

```
using Microsoft.Owin.Hosting;
using Microsoft.WindowsAzure.ServiceRuntime;
using System;
using System.Diagnostics;
using System.Net;
using System.Threading;

namespace WorkerRole1
{
    public class WorkerRole : RoleEntryPoint
    {
        private IDisposable _app = null;

        public override void Run()
        {
            Trace.TraceInformation("WebApiRole entry point called", "Information");

            while (true)
            {
                Thread.Sleep(10000);
                Trace.TraceInformation("Working", "Information");
            }
        }

        public override bool OnStart()
        {
            ServicePointManager.DefaultConnectionLimit = 12;

            var endpoint = RoleEnvironment.CurrentRoleInstance.InstanceEndpoints["Endpoint1"];
            string baseUri = String.Format("{0}://{1}",
                endpoint.Protocol, endpoint.IPEndpoint);

            Trace.TraceInformation(String.Format("Starting OWIN at {0}", baseUri),
                "Information");

            _app = WebApp.Start<Startup>(new StartOptions(url: baseUri));
           return base.OnStart();
        }

        public override void OnStop()
        {
            if (_app != null)
            {
                _app.Dispose();
            }
            base.OnStop();
        }
    }
}
```

Build the solution, and press F5 to run the application locally in the Azure Compute Emulator. Depending on your firewall settings, you might need to allow the emulator through your firewall.

> **NOTE**
>
> If you get an exception like the following, please see this blog post for a workaround. "Could not load file or assembly 'Microsoft.Owin, Version=2.0.2.0, Culture=neutral, PublicKeyToken=31bf3856ad364e35' or one of its dependencies. The located assembly's manifest definition does not match the assembly reference. (Exception from HRESULT: 0x80131040)"

The compute emulator assigns a local IP address to the endpoint. You can find the IP address by viewing the Compute Emulator UI. Right-click the emulator icon in the task bar notification area, and select **Show Compute Emulator UI**.

Find the IP address under Service Deployments, deployment [id], Service Details. Open a web browser and navigate to http://*address*/test/1, where *address* is the IP address assigned by the compute emulator; for example, `http://127.0.0.1:80/test/1`. You should see the response from the Web API controller:

Deploy to Azure

For this step, you must have an Azure account. If you don't already have one, you can create a free trial account in just a couple of minutes. For details, see Microsoft Azure Free Trial.

In Solution Explorer, right-click the AzureApp project. Select **Publish**.

If you are not signed in to your Azure account, click **Sign In**.

After you are signed in, choose a subscription and click **Next**.

Enter a name for the cloud service and choose a region. Click **Create**.

Click **Publish**.

The Azure Activity Log window shows the progress of the deployment. When the app is deployed, browse to http://appname.cloudapp.net/test/1.

Advanced Topics for ASP.NET Web API

2/20/2020 • 2 minutes to read • Edit Online

More advanced topics for ASP.NET Web API development, after you've learned the basics.

- Configuring Web API 2
- Dependency Injection in Web API 2
- Calling a Web API From a .NET Client (C#)
- HTTP Message Handlers in Web API
- HttpClient Message Handlers in Web API
- Sending HTML Form Data in Web API: Form-urlencoded Data
- Sending HTML Form Data in Web API: File Upload and Multipart MIME
- HTTP Cookies in ASP.NET Web API

Configuring ASP.NET Web API 2

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

This topic describes how to configure ASP.NET Web API.

- Configuration Settings
- Configuring Web API with ASP.NET Hosting
- Configuring Web API with OWIN Self-Hosting
- Global Web API Services
- Per-Controller Configuration

Configuration Settings

Web API configuration settings are defined in the HttpConfiguration class.

MEMBER	DESCRIPTION
DependencyResolver	Enables dependency injection for controllers. See Using the Web API Dependency Resolver.
Filters	Action filters.
Formatters	Media-type formatters.
IncludeErrorDetailPolicy	Specifies whether the server should include error details, such as exception messages and stack traces, in HTTP response messages. See IncludeErrorDetailPolicy.
Initializer	A function that performs final initialization of the **HttpConfiguration**.
MessageHandlers	HTTP message handlers.
ParameterBindingRules	A collection of rules for binding parameters on controller actions.
Properties	A generic property bag.
Routes	The collection of routes. See Routing in ASP.NET Web API.
Services	The collection of services. See Services.

Prerequisites

Visual Studio 2017 Community, Professional, or Enterprise edition.

Configuring Web API with ASP.NET Hosting

In an ASP.NET application, configure Web API by calling GlobalConfiguration.Configure in the **Application_Start** method. The **Configure** method takes a delegate with a single parameter of type **HttpConfiguration**. Perform all of your configuration inside the delegate.

Here is an example using an anonymous delegate:

```
using System.Web.Http;
namespace WebApplication1
{
    public class WebApiApplication : System.Web.HttpApplication
    {
        protected void Application_Start()
        {
            GlobalConfiguration.Configure(config =>
            {
                config.MapHttpAttributeRoutes();

                config.Routes.MapHttpRoute(
                    name: "DefaultApi",
                    routeTemplate: "api/{controller}/{id}",
                    defaults: new { id = RouteParameter.Optional }
                );
            });
        }
    }
}
```

In Visual Studio 2017, the "ASP.NET Web Application" project template automatically sets up the configuration code, if you select "Web API" in the **New ASP.NET Project** dialog.

The project template creates a file named WebApiConfig.cs inside the App_Start folder. This code file defines the delegate where you should put your Web API configuration code.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web.Http;

namespace WebApplication1
{
    public static class WebApiConfig
    {
        public static void Register(HttpConfiguration config)
        {
            // TODO: Add any additional configuration code.

            // Web API routes
            config.MapHttpAttributeRoutes();

            config.Routes.MapHttpRoute(
                name: "DefaultApi",
                routeTemplate: "api/{controller}/{id}",
                defaults: new { id = RouteParameter.Optional }
            );
        }
    }
}
```

The project template also adds the code that calls the delegate from **Application_Start**.

```
public class WebApiApplication : System.Web.HttpApplication
{
    protected void Application_Start()
    {
        GlobalConfiguration.Configure(WebApiConfig.Register);
    }
}
```

Configuring Web API with OWIN Self-Hosting

If you are self-hosting with OWIN, create a new **HttpConfiguration** instance. Perform any configuration on this instance, and then pass the instance to the **Owin.UseWebApi** extension method.

```
public class Startup
{
    public void Configuration(IAppBuilder appBuilder)
    {
        HttpConfiguration config = new HttpConfiguration();

        config.Routes.MapHttpRoute(
            name: "DefaultApi",
            routeTemplate: "api/{controller}/{id}",
            defaults: new { id = RouteParameter.Optional }
        );

        appBuilder.UseWebApi(config);
    }
}
```

The tutorial Use OWIN to Self-Host ASP.NET Web API 2 shows the complete steps.

Global Web API Services

The **HttpConfiguration.Services** collection contains a set of global services that Web API uses to perform various tasks, such as controller selection and content negotiation.

> **NOTE**
> The **Services** collection is not a general-purpose mechanism for service discovery or dependency injection. It only stores service types that are known to the Web API framework.

The **Services** collection is initialized with a default set of services, and you can provide your own custom implementations. Some services support multiple instances, while others can have only one instance. (However, you can also provide services at the controller level; see Per-Controller Configuration.

Single-Instance Services

SERVICE	DESCRIPTION
IActionValueBinder	Gets a binding for a parameter.
IApiExplorer	Gets descriptions of the APIs exposed by the application. See Creating a Help Page for a Web API.
IAssembliesResolver	Gets a list of the assemblies for the application. See Routing and Action Selection.
IBodyModelValidator	Validates a model that is read from the request body by a media-type formatter.
IContentNegotiator	Performs content negotiation.
IDocumentationProvider	Provides documentation for APIs. The default is **null**. See Creating a Help Page for a Web API.
IHostBufferPolicySelector	Indicates whether the host should buffer HTTP message entity bodies.
IHttpActionInvoker	Invokes a controller action. See Routing and Action Selection.

SERVICE	DESCRIPTION
IHttpActionSelector	Selects a controller action. See Routing and Action Selection.
IHttpControllerActivator	Activates a controller. See Routing and Action Selection.
IHttpControllerSelector	Selects a controller. See Routing and Action Selection.
IHttpControllerTypeResolver	Provides a list of the Web API controller types in the application. See Routing and Action Selection.
ITraceManager	Initializes the tracing framework. See Tracing in ASP.NET Web API.
ITraceWriter	Provides a trace writer. The default is a "no-op" trace writer. See Tracing in ASP.NET Web API.
IModelValidatorCache	Provides a cache of model validators.

Multiple-Instance Services

SERVICE	DESCRIPTION
IFilterProvider	Returns a list of filters for a controller action.
ModelBinderProvider	Returns a model binder for a given type.
ModelMetadataProvider	Provides metadata for a model.
ModelValidatorProvider	Provides a validator for a model.
ValueProviderFactory	Creates a value provider. For more information, see Mike Stall's blog post How to create a custom value provider in WebAPI

To add a custom implementation to a multi-instance service, call **Add** or **Insert** on the **Services** collection:

```
config.Services.Add(typeof(IFilterProvider), new MyFilterProvider());
```

To replace a single-instance service with a custom implementation, call **Replace** on the **Services** collection:

```
config.Services.Replace(typeof(ITraceWriter), new MyTraceWriter());
```

Per-Controller Configuration

You can override the following settings on a per-controller basis:

- Media-type formatters
- Parameter binding rules
- Services

To do so, define a custom attribute that implements the **IControllerConfiguration** interface. Then apply the attribute to the controller.

The following example replaces the default media-type formatters with a custom formatter.

```
using System;
using System.Web.Http;
using System.Web.Http.Controllers;

namespace WebApplication1.Controllers
{

    public class UseMyFormatterAttribute : Attribute, IControllerConfiguration
    {
        public void Initialize(HttpControllerSettings settings,
            HttpControllerDescriptor descriptor)
        {
            // Clear the formatters list.
            settings.Formatters.Clear();

            // Add a custom media-type formatter.
            settings.Formatters.Add(new MyFormatter());
        }
    }

    [UseMyFormatter]
    public class ValuesController : ApiController
    {
        // Controller methods not shown...
    }
}
```

The **IControllerConfiguration.Initialize** method takes two parameters:

- An **HttpControllerSettings** object
- An **HttpControllerDescriptor** object

The **HttpControllerDescriptor** contains a description of the controller, which you can examine for informational purposes (say, to distinguish between two controllers).

Use the **HttpControllerSettings** object to configure the controller. This object contains the subset of configuration parameters that you can override on a per-controller basis. Any settings that you don't change default to the global **HttpConfiguration** object.

Dependency Injection in ASP.NET Web API 2

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

This tutorial shows how to inject dependencies into your ASP.NET Web API controller.

Software versions used in the tutorial

- Web API 2
- Unity Application Block
- Entity Framework 6 (version 5 also works)

What is Dependency Injection?

A *dependency* is any object that another object requires. For example, it's common to define a repository that handles data access. Let's illustrate with an example. First, we'll define a domain model:

```
public class Product
{
    public int Id { get; set; }
    public string Name { get; set; }
    public decimal Price { get; set; }
}
```

Here is a simple repository class that stores items in a database, using Entity Framework.

```
public class ProductsContext : DbContext
{
    public ProductsContext()
        : base("name=ProductsContext")
    {
    }
    public DbSet<Product> Products { get; set; }
}

public class ProductRepository : IDisposable
{
    private ProductsContext db = new ProductsContext();

    public IEnumerable<Product> GetAll()
    {
        return db.Products;
    }
    public Product GetByID(int id)
    {
        return db.Products.FirstOrDefault(p => p.Id == id);
    }
    public void Add(Product product)
    {
        db.Products.Add(product);
        db.SaveChanges();
    }

    protected void Dispose(bool disposing)
    {
        if (disposing)
        {
            if (db != null)
            {
                db.Dispose();
                db = null;
            }
        }
    }

    public void Dispose()
    {
        Dispose(true);
        GC.SuppressFinalize(this);
    }
}
```

Now let's define a Web API controller that supports GET requests for `Product` entities. (I'm leaving out POST and other methods for simplicity.) Here is a first attempt:

```
public class ProductsController : ApiController
{
    // This line of code is a problem!
    ProductRepository _repository = new ProductRepository();

    public IEnumerable<Product> Get()
    {
        return _repository.GetAll();
    }

    public IHttpActionResult Get(int id)
    {
        var product = _repository.GetByID(id);
        if (product == null)
        {
            return NotFound();
        }
        return Ok(product);
    }
}
```

Notice that the controller class depends on `ProductRepository`, and we are letting the controller create the `ProductRepository` instance. However, it's a bad idea to hard code the dependency in this way, for several reasons.

- If you want to replace `ProductRepository` with a different implementation, you also need to modify the controller class.
- If the `ProductRepository` has dependencies, you must configure these inside the controller. For a large project with multiple controllers, your configuration code becomes scattered across your project.
- It is hard to unit test, because the controller is hard-coded to query the database. For a unit test, you should use a mock or stub repository, which is not possible with the current design.

We can address these problems by *injecting* the repository into the controller. First, refactor the `ProductRepository` class into an interface:

```
public interface IProductRepository
{
    IEnumerable<Product> GetAll();
    Product GetById(int id);
    void Add(Product product);
}

public class ProductRepository : IProductRepository
{
    // Implementation not shown.
}
```

Then provide the `IProductRepository` as a constructor parameter:

```
public class ProductsController : ApiController
{
    private IProductRepository _repository;

    public ProductsController(IProductRepository repository)
    {
        _repository = repository;
    }

    // Other controller methods not shown.
}
```

This example uses constructor injection. You can also use *setter injection*, where you set the dependency through a setter method or property.

But now there is a problem, because your application doesn't create the controller directly. Web API creates the controller when it routes the request, and Web API doesn't know anything about `IProductRepository`. This is where the Web API dependency resolver comes in.

The Web API Dependency Resolver

Web API defines the **IDependencyResolver** interface for resolving dependencies. Here is the definition of the interface:

```
public interface IDependencyResolver : IDependencyScope, IDisposable
{
    IDependencyScope BeginScope();
}

public interface IDependencyScope : IDisposable
{
    object GetService(Type serviceType);
    IEnumerable<object> GetServices(Type serviceType);
}
```

The **IDependencyScope** interface has two methods:

- **GetService** creates one instance of a type.
- **GetServices** creates a collection of objects of a specified type.

The **IDependencyResolver** method inherits **IDependencyScope** and adds the **BeginScope** method. I'll talk about scopes later in this tutorial.

When Web API creates a controller instance, it first calls **IDependencyResolver.GetService**, passing in the controller type. You can use this extensibility hook to create the controller, resolving any dependencies. If **GetService** returns null, Web API looks for a parameterless constructor on the controller class.

Dependency Resolution with the Unity Container

Although you could write a complete **IDependencyResolver** implementation from scratch, the interface is really designed to act as bridge between Web API and existing IoC containers.

An IoC container is a software component that is responsible for managing dependencies. You register types with the container, and then use the container to create objects. The container automatically figures out the dependency relations. Many IoC containers also allow you to control things like object lifetime and scope.

> **NOTE**
> "IoC" stands for "inversion of control", which is a general pattern where a framework calls into application code. An IoC container constructs your objects for you, which "inverts" the usual flow of control.

For this tutorial, we'll use Unity from Microsoft Patterns & Practices. (Other popular libraries include Castle Windsor, Spring.Net, Autofac, Ninject, and StructureMap.) You can use NuGet Package Manager to install Unity. From the **Tools** menu in Visual Studio, select **NuGet Package Manager**, then select **Package Manager Console**. In the Package Manager Console window, type the following command:

```
Install-Package Unity
```

Here is an implementation of **IDependencyResolver** that wraps a Unity container.

```
using Microsoft.Practices.Unity;
using System;
using System.Collections.Generic;
using System.Web.Http.Dependencies;

public class UnityResolver : IDependencyResolver
{
    protected IUnityContainer container;

    public UnityResolver(IUnityContainer container)
    {
        if (container == null)
        {
            throw new ArgumentNullException("container");
        }
        this.container = container;
    }

    public object GetService(Type serviceType)
    {
        try
        {
            return container.Resolve(serviceType);
        }
        catch (ResolutionFailedException)
        {
            return null;
        }
    }

    public IEnumerable<object> GetServices(Type serviceType)
    {
        try
        {
            return container.ResolveAll(serviceType);
        }
        catch (ResolutionFailedException)
        {
            return new List<object>();
        }
    }

    public IDependencyScope BeginScope()
    {
        var child = container.CreateChildContainer();
        return new UnityResolver(child);
    }

    public void Dispose()
    {
        Dispose(true);
    }

    protected virtual void Dispose(bool disposing)
    {
        container.Dispose();
    }
}
```

> **NOTE**
> If the **GetService** method cannot resolve a type, it should return **null**. If the **GetServices** method cannot resolve a type, it should return an empty collection object. Don't throw exceptions for unknown types.

Configuring the Dependency Resolver

Set the dependency resolver on the **DependencyResolver** property of the global **HttpConfiguration** object.

The following code registers the `IProductRepository` interface with Unity and then creates a `UnityResolver`.

```
public static void Register(HttpConfiguration config)
{
    var container = new UnityContainer();
    container.RegisterType<IProductRepository, ProductRepository>(new HierarchicalLifetimeManager());
    config.DependencyResolver = new UnityResolver(container);

    // Other Web API configuration not shown.
}
```

Dependency Scope and Controller Lifetime

Controllers are created per request. To manage object lifetimes, **IDependencyResolver** uses the concept of a *scope*.

The dependency resolver attached to the **HttpConfiguration** object has global scope. When Web API creates a controller, it calls **BeginScope**. This method returns an **IDependencyScope** that represents a child scope.

Web API then calls **GetService** on the child scope to create the controller. When request is complete, Web API calls **Dispose** on the child scope. Use the **Dispose** method to dispose of the controller's dependencies.

How you implement **BeginScope** depends on the IoC container. For Unity, scope corresponds to a child container:

```
public IDependencyScope BeginScope()
{
    var child = container.CreateChildContainer();
    return new UnityResolver(child);
}
```

Most IoC containers have similar equivalents.

Call a Web API From a .NET Client (C#)

5/1/2020 • 7 minutes to read • Edit Online

by Mike Wasson and Rick Anderson

Download Completed Project. Download instructions.

This tutorial shows how to call a web API from a .NET application, using System.Net.Http.HttpClient.

In this tutorial, a client app is written that consumes the following web API:

ACTION	HTTP METHOD	RELATIVE URI
Get a product by ID	GET	/api/products/*id*
Create a new product	POST	/api/products
Update a product	PUT	/api/products/*id*
Delete a product	DELETE	/api/products/*id*

To learn how to implement this API with ASP.NET Web API, see Creating a Web API that Supports CRUD Operations.

For simplicity, the client application in this tutorial is a Windows console application. **HttpClient** is also supported for Windows Phone and Windows Store apps. For more information, see Writing Web API Client Code for Multiple Platforms Using Portable Libraries

NOTE: If you pass base URLs and relative URIs as hard-coded values, be mindful of the rules for utilizing the `HttpClient` API. The `HttpClient.BaseAddress` property should be set to an address with a trailing forward slash (`/`). For example, when passing hard-coded resource URIs to the `HttpClient.GetAsync` method, don't include a leading forward slash. To get a `Product` by ID:

1. Set `client.BaseAddress = new Uri("https://localhost:5001/");`
2. Request a `Product`. For example, `client.GetAsync<Product>("api/products/4");`.

Create the Console Application

In Visual Studio, create a new Windows console app named **HttpClientSample** and paste in the following code:

```
using System;
using System.Net;
using System.Net.Http;
using System.Net.Http.Headers;
using System.Threading.Tasks;

namespace HttpClientSample
{
    public class Product
    {
        public string Id { get; set; }
        public string Name { get; set; }
        public decimal Price { get; set; }
        public string Category { get; set; }
    }
```

```
class Program
{
    static HttpClient client = new HttpClient();

    static void ShowProduct(Product product)
    {
        Console.WriteLine($"Name: {product.Name}\tPrice: " +
            $"{product.Price}\tCategory: {product.Category}");
    }

    static async Task<Uri> CreateProductAsync(Product product)
    {
        HttpResponseMessage response = await client.PostAsJsonAsync(
            "api/products", product);
        response.EnsureSuccessStatusCode();

        // return URI of the created resource.
        return response.Headers.Location;
    }

    static async Task<Product> GetProductAsync(string path)
    {
        Product product = null;
        HttpResponseMessage response = await client.GetAsync(path);
        if (response.IsSuccessStatusCode)
        {
            product = await response.Content.ReadAsAsync<Product>();
        }
        return product;
    }

    static async Task<Product> UpdateProductAsync(Product product)
    {
        HttpResponseMessage response = await client.PutAsJsonAsync(
            $"api/products/{product.Id}", product);
        response.EnsureSuccessStatusCode();

        // Deserialize the updated product from the response body.
        product = await response.Content.ReadAsAsync<Product>();
        return product;
    }

    static async Task<HttpStatusCode> DeleteProductAsync(string id)
    {
        HttpResponseMessage response = await client.DeleteAsync(
            $"api/products/{id}");
        return response.StatusCode;
    }

    static void Main()
    {
        RunAsync().GetAwaiter().GetResult();
    }

    static async Task RunAsync()
    {
        // Update port # in the following line.
        client.BaseAddress = new Uri("http://localhost:64195/");
        client.DefaultRequestHeaders.Accept.Clear();
        client.DefaultRequestHeaders.Accept.Add(
            new MediaTypeWithQualityHeaderValue("application/json"));

        try
        {
            // Create a new product
            Product product = new Product
            {
                Name = "Gizmo",
```

```
                Price = 100,
                Category = "Widgets"
            };

            var url = await CreateProductAsync(product);
            Console.WriteLine($"Created at {url}");

            // Get the product
            product = await GetProductAsync(url.PathAndQuery);
            ShowProduct(product);

            // Update the product
            Console.WriteLine("Updating price...");
            product.Price = 80;
            await UpdateProductAsync(product);

            // Get the updated product
            product = await GetProductAsync(url.PathAndQuery);
            ShowProduct(product);

            // Delete the product
            var statusCode = await DeleteProductAsync(product.Id);
            Console.WriteLine($"Deleted (HTTP Status = {(int)statusCode})");

        }
        catch (Exception e)
        {
            Console.WriteLine(e.Message);
        }

        Console.ReadLine();
    }
  }
}
```

The preceding code is the complete client app.

`RunAsync` runs and blocks until it completes. Most **HttpClient** methods are async, because they perform network I/O. All of the async tasks are done inside `RunAsync`. Normally an app doesn't block the main thread, but this app doesn't allow any interaction.

```
static async Task RunAsync()
{
    // Update port # in the following line.
    client.BaseAddress = new Uri("http://localhost:64195/");
    client.DefaultRequestHeaders.Accept.Clear();
    client.DefaultRequestHeaders.Accept.Add(
        new MediaTypeWithQualityHeaderValue("application/json"));

    try
    {
        // Create a new product
        Product product = new Product
        {
            Name = "Gizmo",
            Price = 100,
            Category = "Widgets"
        };

        var url = await CreateProductAsync(product);
        Console.WriteLine($"Created at {url}");

        // Get the product
        product = await GetProductAsync(url.PathAndQuery);
        ShowProduct(product);

        // Update the product
        Console.WriteLine("Updating price...");
        product.Price = 80;
        await UpdateProductAsync(product);

        // Get the updated product
        product = await GetProductAsync(url.PathAndQuery);
        ShowProduct(product);

        // Delete the product
        var statusCode = await DeleteProductAsync(product.Id);
        Console.WriteLine($"Deleted (HTTP Status = {(int)statusCode})");

    }
    catch (Exception e)
    {
        Console.WriteLine(e.Message);
    }

    Console.ReadLine();
}
```

Install the Web API Client Libraries

Use NuGet Package Manager to install the Web API Client Libraries package.

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**. In the Package Manager Console (PMC), type the following command:

```
Install-Package Microsoft.AspNet.WebApi.Client
```

The preceding command adds the following NuGet packages to the project:

- Microsoft.AspNet.WebApi.Client
- Newtonsoft.Json

Netwonsoft.Json (also known as Json.NET) is a popular high-performance JSON framework for .NET.

Add a Model Class

Examine the `Product` class:

```
public class Product
{
    public string Id { get; set; }
    public string Name { get; set; }
    public decimal Price { get; set; }
    public string Category { get; set; }
}
```

This class matches the data model used by the web API. An app can use **HttpClient** to read a `Product` instance from an HTTP response. The app doesn't have to write any deserialization code.

Create and Initialize HttpClient

Examine the static **HttpClient** property:

```
static HttpClient client = new HttpClient();
```

HttpClient is intended to be instantiated once and reused throughout the life of an application. The following conditions can result in **SocketException** errors:

- Creating a new **HttpClient** instance per request.
- Server under heavy load.

Creating a new **HttpClient** instance per request can exhaust the available sockets.

The following code initializes the **HttpClient** instance:

```
static async Task RunAsync()
{
    // Update port # in the following line.
    client.BaseAddress = new Uri("http://localhost:64195/");
    client.DefaultRequestHeaders.Accept.Clear();
    client.DefaultRequestHeaders.Accept.Add(
        new MediaTypeWithQualityHeaderValue("application/json"));
```

The preceding code:

- Sets the base URI for HTTP requests. Change the port number to the port used in the server app. The app won't work unless port for the server app is used.
- Sets the Accept header to "application/json". Setting this header tells the server to send data in JSON format.

Send a GET request to retrieve a resource

The following code sends a GET request for a product:

```
static async Task<Product> GetProductAsync(string path)
{
    Product product = null;
    HttpResponseMessage response = await client.GetAsync(path);
    if (response.IsSuccessStatusCode)
    {
        product = await response.Content.ReadAsAsync<Product>();
    }
    return product;
}
```

The **GetAsync** method sends the HTTP GET request. When the method completes, it returns an **HttpResponseMessage** that contains the HTTP response. If the status code in the response is a success code, the response body contains the JSON representation of a product. Call **ReadAsAsync** to deserialize the JSON payload to a `Product` instance. The **ReadAsAsync** method is asynchronous because the response body can be arbitrarily large.

HttpClient does not throw an exception when the HTTP response contains an error code. Instead, the **IsSuccessStatusCode** property is **false** if the status is an error code. If you prefer to treat HTTP error codes as exceptions, call HttpResponseMessage.EnsureSuccessStatusCode on the response object. `EnsureSuccessStatusCode` throws an exception if the status code falls outside the range 200–299. Note that **HttpClient** can throw exceptions for other reasons — for example, if the request times out.

Media-Type Formatters to Deserialize

When **ReadAsAsync** is called with no parameters, it uses a default set of *media formatters* to read the response body. The default formatters support JSON, XML, and Form-url-encoded data.

Instead of using the default formatters, you can provide a list of formatters to the **ReadAsAsync** method. Using a list of formatters is useful if you have a custom media-type formatter:

```
var formatters = new List<MediaTypeFormatter>() {
    new MyCustomFormatter(),
    new JsonMediaTypeFormatter(),
    new XmlMediaTypeFormatter()
};
resp.Content.ReadAsAsync<IEnumerable<Product>>(formatters);
```

For more information, see Media Formatters in ASP.NET Web API 2

Sending a POST Request to Create a Resource

The following code sends a POST request that contains a `Product` instance in JSON format:

```
static async Task<Uri> CreateProductAsync(Product product)
{
    HttpResponseMessage response = await client.PostAsJsonAsync(
        "api/products", product);
    response.EnsureSuccessStatusCode();

    // return URI of the created resource.
    return response.Headers.Location;
}
```

The **PostAsJsonAsync** method:

- Serializes an object to JSON.
- Sends the JSON payload in a POST request.

If the request succeeds:

- It should return a 201 (Created) response.
- The response should include the URL of the created resources in the Location header.

Sending a PUT Request to Update a Resource

The following code sends a PUT request to update a product:

```
static async Task<Product> UpdateProductAsync(Product product)
{
    HttpResponseMessage response = await client.PutAsJsonAsync(
        $"api/products/{product.Id}", product);
    response.EnsureSuccessStatusCode();

    // Deserialize the updated product from the response body.
    product = await response.Content.ReadAsAsync<Product>();
    return product;
}
```

The **PutAsJsonAsync** method works like **PostAsJsonAsync**, except that it sends a PUT request instead of POST.

Sending a DELETE Request to Delete a Resource

The following code sends a DELETE request to delete a product:

```
static async Task<HttpStatusCode> DeleteProductAsync(string id)
{
    HttpResponseMessage response = await client.DeleteAsync(
        $"api/products/{id}");
    return response.StatusCode;
}
```

Like GET, a DELETE request does not have a request body. You don't need to specify JSON or XML format with DELETE.

Test the sample

To test the client app:

1. Download and run the server app. Download instructions. Verify the server app is working. For example, `http://localhost:64195/api/products` should return a list of products.

2. Set the base URI for HTTP requests. Change the port number to the port used in the server app.

   ```
   static async Task RunAsync()
   {
       // Update port # in the following line.
       client.BaseAddress = new Uri("http://localhost:64195/");
       client.DefaultRequestHeaders.Accept.Clear();
       client.DefaultRequestHeaders.Accept.Add(
           new MediaTypeWithQualityHeaderValue("application/json"));
   ```

3. Run the client app. The following output is produced:

```
Created at http://localhost:64195/api/products/4
Name: Gizmo     Price: 100.0    Category: Widgets
Updating price...
Name: Gizmo     Price: 80.0     Category: Widgets
Deleted (HTTP Status = 204)
```

HTTP Message Handlers in ASP.NET Web API

2/20/2020 • 7 minutes to read • Edit Online

by Mike Wasson

A *message handler* is a class that receives an HTTP request and returns an HTTP response. Message handlers derive from the abstract **HttpMessageHandler** class.

Typically, a series of message handlers are chained together. The first handler receives an HTTP request, does some processing, and gives the request to the next handler. At some point, the response is created and goes back up the chain. This pattern is called a *delegating* handler.

Server-Side Message Handlers

On the server side, the Web API pipeline uses some built-in message handlers:

- **HttpServer** gets the request from the host.
- **HttpRoutingDispatcher** dispatches the request based on the route.
- **HttpControllerDispatcher** sends the request to a Web API controller.

You can add custom handlers to the pipeline. Message handlers are good for cross-cutting concerns that operate at the level of HTTP messages (rather than controller actions). For example, a message handler might:

- Read or modify request headers.
- Add a response header to responses.
- Validate requests before they reach the controller.

This diagram shows two custom handlers inserted into the pipeline:

> **NOTE**
>
> On the client side, HttpClient also uses message handlers. For more information, see HttpClient Message Handlers.

Custom Message Handlers

To write a custom message handler, derive from **System.Net.Http.DelegatingHandler** and override the **SendAsync** method. This method has the following signature:

```
Task<HttpResponseMessage> SendAsync(
    HttpRequestMessage request, CancellationToken cancellationToken);
```

The method takes an **HttpRequestMessage** as input and asynchronously returns an **HttpResponseMessage**. A typical implementation does the following:

1. Process the request message.
2. Call `base.SendAsync` to send the request to the inner handler.
3. The inner handler returns a response message. (This step is asynchronous.)
4. Process the response and return it to the caller.

Here is a trivial example:

```
public class MessageHandler1 : DelegatingHandler
{
    protected async override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        Debug.WriteLine("Process request");
        // Call the inner handler.
        var response = await base.SendAsync(request, cancellationToken);
        Debug.WriteLine("Process response");
        return response;
    }
}
```

> **NOTE**
> The call to `base.SendAsync` is asynchronous. If the handler does any work after this call, use the **await** keyword, as shown.

A delegating handler can also skip the inner handler and directly create the response:

```
public class MessageHandler2 : DelegatingHandler
{
    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        // Create the response.
        var response = new HttpResponseMessage(HttpStatusCode.OK)
        {
            Content = new StringContent("Hello!")
        };

        // Note: TaskCompletionSource creates a task that does not contain a delegate.
        var tsc = new TaskCompletionSource<HttpResponseMessage>();
        tsc.SetResult(response);   // Also sets the task state to "RanToCompletion"
        return tsc.Task;
    }
}
```

If a delegating handler creates the response without calling `base.SendAsync`, the request skips the rest of the pipeline. This can be useful for a handler that validates the request (creating an error response).

Adding a Handler to the Pipeline

To add a message handler on the server side, add the handler to the **HttpConfiguration.MessageHandlers** collection. If you used the "ASP.NET MVC 4 Web Application" template to create the project, you can do this inside the **WebApiConfig** class:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.MessageHandlers.Add(new MessageHandler1());
        config.MessageHandlers.Add(new MessageHandler2());

        // Other code not shown...
    }
}
```

Message handlers are called in the same order that they appear in **MessageHandlers** collection. Because they are nested, the response message travels in the other direction. That is, the last handler is the first to get the

response message.

Notice that you don't need to set the inner handlers; the Web API framework automatically connects the message handlers.

If you are self-hosting, create an instance of the **HttpSelfHostConfiguration** class and add the handlers to the **MessageHandlers** collection.

```
var config = new HttpSelfHostConfiguration("http://localhost");
config.MessageHandlers.Add(new MessageHandler1());
config.MessageHandlers.Add(new MessageHandler2());
```

Now let's look at some examples of custom message handlers.

Example: X-HTTP-Method-Override

X-HTTP-Method-Override is a non-standard HTTP header. It is designed for clients that cannot send certain HTTP request types, such as PUT or DELETE. Instead, the client sends a POST request and sets the X-HTTP-Method-Override header to the desired method. For example:

```
X-HTTP-Method-Override: PUT
```

Here is a message handler that adds support for X-HTTP-Method-Override:

```
public class MethodOverrideHandler : DelegatingHandler
{
    readonly string[] _methods = { "DELETE", "HEAD", "PUT" };
    const string _header = "X-HTTP-Method-Override";

    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        // Check for HTTP POST with the X-HTTP-Method-Override header.
        if (request.Method == HttpMethod.Post && request.Headers.Contains(_header))
        {
            // Check if the header value is in our methods list.
            var method = request.Headers.GetValues(_header).FirstOrDefault();
            if (_methods.Contains(method, StringComparer.InvariantCultureIgnoreCase))
            {
                // Change the request method.
                request.Method = new HttpMethod(method);
            }
        }
        return base.SendAsync(request, cancellationToken);
    }
}
```

In the **SendAsync** method, the handler checks whether the request message is a POST request, and whether it contains the X-HTTP-Method-Override header. If so, it validates the header value, and then modifies the request method. Finally, the handler calls `base.SendAsync` to pass the message to the next handler.

When the request reaches the **HttpControllerDispatcher** class, **HttpControllerDispatcher** will route the request based on the updated request method.

Example: Adding a Custom Response Header

Here is a message handler that adds a custom header to every response message:

```
// .Net 4.5
public class CustomHeaderHandler : DelegatingHandler
{
    async protected override Task<HttpResponseMessage> SendAsync(
            HttpRequestMessage request, CancellationToken cancellationToken)
    {
        HttpResponseMessage response = await base.SendAsync(request, cancellationToken);
        response.Headers.Add("X-Custom-Header", "This is my custom header.");
        return response;
    }
}
```

First, the handler calls `base.SendAsync` to pass the request to the inner message handler. The inner handler returns a response message, but it does so asynchronously using a **Task<T>** object. The response message is not available until `base.SendAsync` completes asynchronously.

This example uses the **await** keyword to perform work asynchronously after `SendAsync` completes. If you are targeting .NET Framework 4.0, use the **Task**<T>.**ContinueWith** method:

```
public class CustomHeaderHandler : DelegatingHandler
{
    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        return base.SendAsync(request, cancellationToken).ContinueWith(
            (task) =>
            {
                HttpResponseMessage response = task.Result;
                response.Headers.Add("X-Custom-Header", "This is my custom header.");
                return response;
            }
        );
    }
}
```

Example: Checking for an API Key

Some web services require clients to include an API key in their request. The following example shows how a message handler can check requests for a valid API key:

```
public class ApiKeyHandler : DelegatingHandler
{
    public string Key { get; set; }

    public ApiKeyHandler(string key)
    {
        this.Key = key;
    }

    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        if (!ValidateKey(request))
        {
            var response = new HttpResponseMessage(HttpStatusCode.Forbidden);
            var tsc = new TaskCompletionSource<HttpResponseMessage>();
            tsc.SetResult(response);
            return tsc.Task;
        }
        return base.SendAsync(request, cancellationToken);
    }

    private bool ValidateKey(HttpRequestMessage message)
    {
        var query = message.RequestUri.ParseQueryString();
        string key = query["key"];
        return (key == Key);
    }
}
```

This handler looks for the API key in the URI query string. (For this example, we assume that the key is a static string. A real implementation would probably use more complex validation.) If the query string contains the key, the handler passes the request to the inner handler.

If the request does not have a valid key, the handler creates a response message with status 403, Forbidden. In this case, the handler does not call `base.SendAsync`, so the inner handler never receives the request, nor does the controller. Therefore, the controller can assume that all incoming requests have a valid API key.

> **NOTE**
> If the API key applies only to certain controller actions, consider using an action filter instead of a message handler. Action filters run after URI routing is performed.

Per-Route Message Handlers

Handlers in the **HttpConfiguration.MessageHandlers** collection apply globally.

Alternatively, you can add a message handler to a specific route when you define the route:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.Routes.MapHttpRoute(
            name: "Route1",
            routeTemplate: "api/{controller}/{id}",
            defaults: new { id = RouteParameter.Optional }
        );

        config.Routes.MapHttpRoute(
            name: "Route2",
            routeTemplate: "api2/{controller}/{id}",
            defaults: new { id = RouteParameter.Optional },
            constraints: null,
            handler: new MessageHandler2()  // per-route message handler
        );

        config.MessageHandlers.Add(new MessageHandler1());  // global message handler
    }
}
```

In this example, if the request URI matches "Route2", the request is dispatched to `MessageHandler2`. The following diagram shows the pipeline for these two routes:

Notice that `MessageHandler2` replaces the default **HttpControllerDispatcher**. In this example, `MessageHandler2` creates the response, and requests that match "Route2" never go to a controller. This lets you replace the entire Web API controller mechanism with your own custom endpoint.

Alternatively, a per-route message handler can delegate to **HttpControllerDispatcher**, which then dispatches to a controller.

The following code shows how to configure this route:

```
// List of delegating handlers.
DelegatingHandler[] handlers = new DelegatingHandler[] {
    new MessageHandler3()
};

// Create a message handler chain with an end-point.
var routeHandlers = HttpClientFactory.CreatePipeline(
    new HttpControllerDispatcher(config), handlers);

config.Routes.MapHttpRoute(
    name: "Route2",
    routeTemplate: "api2/{controller}/{id}",
    defaults: new { id = RouteParameter.Optional },
    constraints: null,
    handler: routeHandlers
);
```

HttpClient Message Handlers in ASP.NET Web API

2/20/2020 • 2 minutes to read • Edit Online

by Mike Wasson

A *message handler* is a class that receives an HTTP request and returns an HTTP response.

Typically, a series of message handlers are chained together. The first handler receives an HTTP request, does some processing, and gives the request to the next handler. At some point, the response is created and goes back up the chain. This pattern is called a *delegating* handler.

On the client side, the **HttpClient** class uses a message handler to process requests. The default handler is **HttpClientHandler**, which sends the request over the network and gets the response from the server. You can insert custom message handlers into the client pipeline:

> **NOTE**
>
> ASP.NET Web API also uses message handlers on the server side. For more information, see HTTP Message Handlers.

Custom Message Handlers

To write a custom message handler, derive from **System.Net.Http.DelegatingHandler** and override the **SendAsync** method. Here is the method signature:

```
Task<HttpResponseMessage> SendAsync(
    HttpRequestMessage request, CancellationToken cancellationToken);
```

The method takes an **HttpRequestMessage** as input and asynchronously returns an **HttpResponseMessage**. A

typical implementation does the following:

1. Process the request message.
2. Call `base.SendAsync` to send the request to the inner handler.
3. The inner handler returns a response message. (This step is asynchronous.)
4. Process the response and return it to the caller.

The following example shows a message handler that adds a custom header to the outgoing request:

```
class MessageHandler1 : DelegatingHandler
{
    private int _count = 0;

    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, System.Threading.CancellationToken cancellationToken)
    {
        System.Threading.Interlocked.Increment(ref _count);
        request.Headers.Add("X-Custom-Header", _count.ToString());
        return base.SendAsync(request, cancellationToken);
    }
}
```

The call to `base.SendAsync` is asynchronous. If the handler does any work after this call, use the **await** keyword to resume execution after the method completes. The following example shows a handler that logs error codes. The logging itself is not very interesting, but the example shows how to get at the response inside the handler.

```
class LoggingHandler : DelegatingHandler
{
    StreamWriter _writer;

    public LoggingHandler(Stream stream)
    {
        _writer = new StreamWriter(stream);
    }

    protected override async Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, System.Threading.CancellationToken cancellationToken)
    {
        var response = await base.SendAsync(request, cancellationToken);

        if (!response.IsSuccessStatusCode)
        {
            _writer.WriteLine("{0}\t{1}\t{2}", request.RequestUri,
                (int)response.StatusCode, response.Headers.Date);
        }
        return response;
    }

    protected override void Dispose(bool disposing)
    {
        if (disposing)
        {
            _writer.Dispose();
        }
        base.Dispose(disposing);
    }
}
```

Adding Message Handlers to the Client Pipeline

To add custom handlers to **HttpClient**, use the **HttpClientFactory.Create** method:

```
HttpClient client = HttpClientFactory.Create(new Handler1(), new Handler2(), new Handler3());
```

Message handlers are called in the order that you pass them into the `Create` method. Because handlers are nested, the response message travels in the other direction. That is, the last handler is the first to get the response message.

Sending HTML Form Data in ASP.NET Web API: Form-urlencoded Data

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

Part 1: Form-urlencoded Data

This article shows how to post form-urlencoded data to a Web API controller.

- Overview of HTML Forms
- Sending Complex Types
- Sending Form Data via AJAX
- Sending Simple Types

> **NOTE**
>
> Download the completed project.

Overview of HTML Forms

HTML forms use either GET or POST to send data to the server. The **method** attribute of the **form** element gives the HTTP method:

```
<form action="api/values" method="post">
```

The default method is GET. If the form uses GET, the form data is encoded in the URI as a query string. If the form uses POST, the form data is placed in the request body. For POSTed data, the **enctype** attribute specifies the format of the request body:

ENCTYPE	DESCRIPTION
application/x-www-form-urlencoded	Form data is encoded as name/value pairs, similar to a URI query string. This is the default format for POST.
multipart/form-data	Form data is encoded as a multipart MIME message. Use this format if you are uploading a file to the server.

Part 1 of this article looks at x-www-form-urlencoded format. Part 2 describes multipart MIME.

Sending Complex Types

Typically, you will send a complex type, composed of values taken from several form controls. Consider the following model that represents a status update:

```
namespace FormEncode.Models
{
    using System;
    using System.ComponentModel.DataAnnotations;

    public class Update
    {
        [Required]
        [MaxLength(140)]
        public string Status { get; set; }

        public DateTime Date { get; set; }
    }
}
```

Here is a Web API controller that accepts an `Update` object via POST.

```
namespace FormEncode.Controllers
{
    using FormEncode.Models;
    using System;
    using System.Collections.Generic;
    using System.Net;
    using System.Net.Http;
    using System.Web;
    using System.Web.Http;

    public class UpdatesController : ApiController
    {
        static readonly Dictionary<Guid, Update> updates = new Dictionary<Guid, Update>();

        [HttpPost]
        [ActionName("Complex")]
        public HttpResponseMessage PostComplex(Update update)
        {
            if (ModelState.IsValid && update != null)
            {
                // Convert any HTML markup in the status text.
                update.Status = HttpUtility.HtmlEncode(update.Status);

                // Assign a new ID.
                var id = Guid.NewGuid();
                updates[id] = update;

                // Create a 201 response.
                var response = new HttpResponseMessage(HttpStatusCode.Created)
                {
                    Content = new StringContent(update.Status)
                };
                response.Headers.Location =
                    new Uri(Url.Link("DefaultApi", new { action = "status", id = id }));
                return response;
            }
            else
            {
                return Request.CreateResponse(HttpStatusCode.BadRequest);
            }
        }

        [HttpGet]
        public Update Status(Guid id)
        {
            Update update;
            if (updates.TryGetValue(id, out update))
            {
                return update;
            }
            else
            {
                throw new HttpResponseException(HttpStatusCode.NotFound);
            }
        }

    }
}
```

NOTE

This controller uses action-based routing, so the route template is "api/{controller}/{action}/{id}". The client will post the data to "/api/updates/complex".

Now let's write an HTML form for users to submit a status update.

```
<h1>Complex Type</h1>
<form id="form1" method="post" action="api/updates/complex"
    enctype="application/x-www-form-urlencoded">
    <div>
        <label for="status">Status</label>
    </div>
    <div>
        <input name="status" type="text" />
    </div>
    <div>
        <label for="date">Date</label>
    </div>
    <div>
        <input name="date" type="text" />
    </div>
    <div>
        <input type="submit" value="Submit" />
    </div>
</form>
```

Notice that the **action** attribute on the form is the URI of our controller action. Here is the form with some values entered in:

When the user clicks Submit, the browser sends an HTTP request similar to the following:

```
POST http://localhost:38899/api/updates/complex HTTP/1.1
Accept: text/html, application/xhtml+xml, */*
User-Agent: Mozilla/5.0 (compatible; MSIE 9.0; Windows NT 6.1; WOW64; Trident/5.0)
Content-Type: application/x-www-form-urlencoded
Content-Length: 47

status=Shopping+at+the+mall.&date=6%2F15%2F2012
```

Notice that the request body contains the form data, formatted as name/value pairs. Web API automatically converts the name/value pairs into an instance of the `Update` class.

Sending Form Data via AJAX

When a user submits a form, the browser navigates away from the current page and renders the body of the response message. That's OK when the response is an HTML page. With a web API, however, the response body is usually either empty or contains structured data, such as JSON. In that case, it makes more sense to send the form data using an AJAX request, so that the page can process the response.

The following code shows how to post form data using jQuery.

```
<script type="text/javascript">
    $("#form1").submit(function () {
        var jqxhr = $.post('api/updates/complex', $('#form1').serialize())
            .success(function () {
                var loc = jqxhr.getResponseHeader('Location');
                var a = $('<a/>', { href: loc, text: loc });
                $('#message').html(a);
            })
            .error(function () {
                $('#message').html("Error posting the update.");
            });
        return false;
    });
</script>
```

The jQuery **submit** function replaces the form action with a new function. This overrides the default behavior of the Submit button. The **serialize** function serializes the form data into name/value pairs. To send the form data to the server, call `$.post()`.

When the request completes, the `.success()` or `.error()` handler displays an appropriate message to the user.

Sending Simple Types

In the previous sections, we sent a complex type, which Web API deserialized to an instance of a model class. You can also send simple types, such as a string.

> **NOTE**
> Before sending a simple type, consider wrapping the value in a complex type instead. This gives you the benefits of model validation on the server side, and makes it easier to extend your model if needed.

The basic steps to send a simple type are the same, but there are two subtle differences. First, in the controller, you must decorate the parameter name with the **FromBody** attribute.

```
[HttpPost]
[ActionName("Simple")]
public HttpResponseMessage PostSimple([FromBody] string value)
{
    if (value != null)
    {
        Update update = new Update()
        {
            Status = HttpUtility.HtmlEncode(value),
            Date = DateTime.UtcNow
        };

        var id = Guid.NewGuid();
        updates[id] = update;

        var response = new HttpResponseMessage(HttpStatusCode.Created)
        {
            Content = new StringContent(update.Status)
        };
        response.Headers.Location =
            new Uri(Url.Link("DefaultApi", new { action = "status", id = id }));
        return response;
    }
    else
    {
        return Request.CreateResponse(HttpStatusCode.BadRequest);
    }
```

By default, Web API tries to get simple types from the request URI. The **FromBody** attribute tells Web API to read the value from the request body.

> **NOTE**
> Web API reads the response body at most once, so only one parameter of an action can come from the request body. If you need to get multiple values from the request body, define a complex type.

Second, the client needs to send the value with the following format:

```
=value
```

Specifically, the name portion of the name/value pair must be empty for a simple type. Not all browsers support this for HTML forms, but you create this format in script as follows:

```
$.post('api/updates/simple', { "": $('#status1').val() });
```

Here is an example form:

```
<h1>Simple Type</h1>
<form id="form2">
    <div>
        <label for="status">Status</label>
    </div>
    <div>
        <input id="status1" type="text" />
    </div>
    <div>
        <input type="submit" value="Submit" />
    </div>
</form>
```

And here is the script to submit the form value. The only difference from the previous script is the argument passed into the **post** function.

```
$('#form2').submit(function () {
    var jqxhr = $.post('api/updates/simple', { "": $('#status1').val() })
        .success(function () {
            var loc = jqxhr.getResponseHeader('Location');
            var a = $('<a/>', { href: loc, text: loc });
            $('#message').html(a);
        })
        .error(function () {
            $('#message').html("Error posting the update.");
        });
    return false;
});
```

You can use the same approach to send an array of simple types:

```
$.post('api/updates/postlist', { "": ["update one", "update two", "update three"] });
```

Part 2: File Upload and Multipart MIME

Sending HTML Form Data in ASP.NET Web API: File Upload and Multipart MIME

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

Part 2: File Upload and Multipart MIME

This tutorial shows how to upload files to a web API. It also describes how to process multipart MIME data.

> **NOTE**
>
> Download the completed project.

Here is an example of an HTML form for uploading a file:

```
<form name="form1" method="post" enctype="multipart/form-data" action="api/upload">
    <div>
        <label for="caption">Image Caption</label>
        <input name="caption" type="text" />
    </div>
    <div>
        <label for="image1">Image File</label>
        <input name="image1" type="file" />
    </div>
    <div>
        <input type="submit" value="Submit" />
    </div>
</form>
```

This form contains a text input control and a file input control. When a form contains a file input control, the **enctype** attribute should always be "multipart/form-data", which specifies that the form will be sent as a multipart MIME message.

The format of a multipart MIME message is easiest to understand by looking at an example request:

```
POST http://localhost:50460/api/values/1 HTTP/1.1
User-Agent: Mozilla/5.0 (Windows NT 6.1; WOW64; rv:12.0) Gecko/20100101 Firefox/12.0
Accept: text/html,application/xhtml+xml,application/xml;q=0.9,*/*;q=0.8
Accept-Language: en-us,en;q=0.5
Accept-Encoding: gzip, deflate
Content-Type: multipart/form-data; boundary=---------------------------41184676334
Content-Length: 29278

-----------------------------41184676334
Content-Disposition: form-data; name="caption"

Summer vacation
-----------------------------41184676334
Content-Disposition: form-data; name="image1"; filename="GrandCanyon.jpg"
Content-Type: image/jpeg

(Binary data not shown)
-----------------------------41184676334--
```

This message is divided into two *parts*, one for each form control. Part boundaries are indicated by the lines that start with dashes.

> **NOTE**
> The part boundary includes a random component ("41184676334") to ensure that the boundary string does not accidentally appear inside a message part.

Each message part contains one or more headers, followed by the part contents.

- The Content-Disposition header includes the name of the control. For files, it also contains the file name.
- The Content-Type header describes the data in the part. If this header is omitted, the default is text/plain.

In the previous example, the user uploaded a file named GrandCanyon.jpg, with content type image/jpeg; and the value of the text input was "Summer Vacation".

File Upload

Now let's look at a Web API controller that reads files from a multipart MIME message. The controller will read the files asynchronously. Web API supports asynchronous actions using the task-based programming model. First, here is the code if you are targeting .NET Framework 4.5, which supports the **async** and **await** keywords.

```
using System.Diagnostics;
using System.Net;
using System.Net.Http;
using System.Threading.Tasks;
using System.Web;
using System.Web.Http;

public class UploadController : ApiController
{
    public async Task<HttpResponseMessage> PostFormData()
    {
        // Check if the request contains multipart/form-data.
        if (!Request.Content.IsMimeMultipartContent())
        {
            throw new HttpResponseException(HttpStatusCode.UnsupportedMediaType);
        }

        string root = HttpContext.Current.Server.MapPath("~/App_Data");
        var provider = new MultipartFormDataStreamProvider(root);

        try
        {
            // Read the form data.
            await Request.Content.ReadAsMultipartAsync(provider);

            // This illustrates how to get the file names.
            foreach (MultipartFileData file in provider.FileData)
            {
                Trace.WriteLine(file.Headers.ContentDisposition.FileName);
                Trace.WriteLine("Server file path: " + file.LocalFileName);
            }
            return Request.CreateResponse(HttpStatusCode.OK);
        }
        catch (System.Exception e)
        {
            return Request.CreateErrorResponse(HttpStatusCode.InternalServerError, e);
        }
    }

}
```

Notice that the controller action does not take any parameters. That's because we process the request body inside the action, without invoking a media-type formatter.

The **IsMultipartContent** method checks whether the request contains a multipart MIME message. If not, the controller returns HTTP status code 415 (Unsupported Media Type).

The **MultipartFormDataStreamProvider** class is a helper object that allocates file streams for uploaded files. To read the multipart MIME message, call the **ReadAsMultipartAsync** method. This method extracts all of the message parts and writes them into the streams provided by the **MultipartFormDataStreamProvider**.

When the method completes, you can get information about the files from the **FileData** property, which is a collection of **MultipartFileData** objects.

- **MultipartFileData.FileName** is the local file name on the server, where the file was saved.
- **MultipartFileData.Headers** contains the part header (*not* the request header). You can use this to access the Content_Disposition and Content-Type headers.

As the name suggests, **ReadAsMultipartAsync** is an asynchronous method. To perform work after the method completes, use a continuation task (.NET 4.0) or the **await** keyword (.NET 4.5).

Here is the .NET Framework 4.0 version of the previous code:

```
public Task<HttpResponseMessage> PostFormData()
{
    // Check if the request contains multipart/form-data.
    if (!Request.Content.IsMimeMultipartContent())
    {
        throw new HttpResponseException(HttpStatusCode.UnsupportedMediaType);
    }

    string root = HttpContext.Current.Server.MapPath("~/App_Data");
    var provider = new MultipartFormDataStreamProvider(root);

    // Read the form data and return an async task.
    var task = Request.Content.ReadAsMultipartAsync(provider).
        ContinueWith<HttpResponseMessage>(t =>
        {
            if (t.IsFaulted || t.IsCanceled)
            {
                Request.CreateErrorResponse(HttpStatusCode.InternalServerError, t.Exception);
            }

            // This illustrates how to get the file names.
            foreach (MultipartFileData file in provider.FileData)
            {
                Trace.WriteLine(file.Headers.ContentDisposition.FileName);
                Trace.WriteLine("Server file path: " + file.LocalFileName);
            }
            return Request.CreateResponse(HttpStatusCode.OK);
        });

    return task;
}
```

Reading Form Control Data

The HTML form that I showed earlier had a text input control.

```
<div>
        <label for="caption">Image Caption</label>
        <input name="caption" type="text" />
    </div>
```

You can get the value of the control from the **FormData** property of the **MultipartFormDataStreamProvider**.

```
public async Task<HttpResponseMessage> PostFormData()
{
    if (!Request.Content.IsMimeMultipartContent())
    {
        throw new HttpResponseException(HttpStatusCode.UnsupportedMediaType);
    }

    string root = HttpContext.Current.Server.MapPath("~/App_Data");
    var provider = new MultipartFormDataStreamProvider(root);

    try
    {
        await Request.Content.ReadAsMultipartAsync(provider);

        // Show all the key-value pairs.
        foreach (var key in provider.FormData.AllKeys)
        {
            foreach (var val in provider.FormData.GetValues(key))
            {
                Trace.WriteLine(string.Format("{0}: {1}", key, val));
            }
        }

        return Request.CreateResponse(HttpStatusCode.OK);
    }
    catch (System.Exception e)
    {
        return Request.CreateErrorResponse(HttpStatusCode.InternalServerError, e);
    }
}
```

FormData is a **NameValueCollection** that contains name/value pairs for the form controls. The collection can contain duplicate keys. Consider this form:

```
<form name="trip_search" method="post" enctype="multipart/form-data" action="api/upload">
    <div>
        <input type="radio" name="trip" value="round-trip"/>
        Round-Trip
    </div>
    <div>
        <input type="radio" name="trip" value="one-way"/>
        One-Way
    </div>

    <div>
        <input type="checkbox" name="options" value="nonstop" />
        Only show non-stop flights
    </div>
    <div>
        <input type="checkbox" name="options" value="airports" />
        Compare nearby airports
    </div>
    <div>
        <input type="checkbox" name="options" value="dates" />
        My travel dates are flexible
    </div>

    <div>
        <label for="seat">Seating Preference</label>
        <select name="seat">
            <option value="aisle">Aisle</option>
            <option value="window">Window</option>
            <option value="center">Center</option>
            <option value="none">No Preference</option>
        </select>
    </div>
</form>
```

The request body might look like this:

```
-----------------------------7dc1d13623304d6
Content-Disposition: form-data; name="trip"

round-trip
-----------------------------7dc1d13623304d6
Content-Disposition: form-data; name="options"

nonstop
-----------------------------7dc1d13623304d6
Content-Disposition: form-data; name="options"

dates
-----------------------------7dc1d13623304d6
Content-Disposition: form-data; name="seat"

window
-----------------------------7dc1d13623304d6--
```

In that case, the **FormData** collection would contain the following key/value pairs:

- trip: round-trip
- options: nonstop
- options: dates
- seat: window

HTTP Cookies in ASP.NET Web API

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

This topic describes how to send and receive HTTP cookies in Web API.

Background on HTTP Cookies

This section gives a brief overview of how cookies are implemented at the HTTP level. For details, consult RFC 6265.

A cookie is a piece of data that a server sends in the HTTP response. The client (optionally) stores the cookie and returns it on subsequent requests. This allows the client and server to share state. To set a cookie, the server includes a Set-Cookie header in the response. The format of a cookie is a name-value pair, with optional attributes. For example:

```
Set-Cookie: session-id=1234567
```

Here is an example with attributes:

```
Set-Cookie: session-id=1234567; max-age=86400; domain=example.com; path=/;
```

To return a cookie to the server, the client includes a Cookie header in later requests.

```
Cookie: session-id=1234567
```

An HTTP response can include multiple Set-Cookie headers.

```
Set-Cookie: session-token=abcdef;
Set-Cookie: session-id=1234567;
```

The client returns multiple cookies using a single Cookie header.

```
Cookie: session-id=1234567; session-token=abcdef;
```

The scope and duration of a cookie are controlled by following attributes in the Set-Cookie header:

- **Domain**: Tells the client which domain should receive the cookie. For example, if the domain is "example.com", the client returns the cookie to every subdomain of example.com. If not specified, the domain is the origin server.
- **Path**: Restricts the cookie to the specified path within the domain. If not specified, the path of the request URI is used.
- **Expires**: Sets an expiration date for the cookie. The client deletes the cookie when it expires.
- **Max-Age**: Sets the maximum age for the cookie. The client deletes the cookie when it reaches the maximum age.

If both `Expires` and `Max-Age` are set, `Max-Age` takes precedence. If neither is set, the client deletes the cookie when the current session ends. (The exact meaning of "session" is determined by the user-agent.)

However, be aware that clients may ignore cookies. For example, a user might disable cookies for privacy reasons. Clients may delete cookies before they expire, or limit the number of cookies stored. For privacy reasons, clients often reject "third party" cookies, where the domain does not match the origin server. In short, the server should not rely on getting back the cookies that it sets.

Cookies in Web API

To add a cookie to an HTTP response, create a **CookieHeaderValue** instance that represents the cookie. Then call the **AddCookies** extension method, which is defined in the **System.Net.Http.HttpResponseHeadersExtensions** class, to add the cookie.

For example, the following code adds a cookie within a controller action:

```
public HttpResponseMessage Get()
{
    var resp = new HttpResponseMessage();

    var cookie = new CookieHeaderValue("session-id", "12345");
    cookie.Expires = DateTimeOffset.Now.AddDays(1);
    cookie.Domain = Request.RequestUri.Host;
    cookie.Path = "/";

    resp.Headers.AddCookies(new CookieHeaderValue[] { cookie });
    return resp;
}
```

Notice that **AddCookies** takes an array of **CookieHeaderValue** instances.

To extract the cookies from a client request, call the **GetCookies** method:

```
string sessionId = "";

CookieHeaderValue cookie = Request.Headers.GetCookies("session-id").FirstOrDefault();
if (cookie != null)
{
    sessionId = cookie["session-id"].Value;
}
```

A **CookieHeaderValue** contains a collection of **CookieState** instances. Each **CookieState** represents one cookie. Use the indexer method to get a **CookieState** by name, as shown.

Structured Cookie Data

Many browsers limit how many cookies they will store—both the total number, and the number per domain. Therefore, it can be useful to put structured data into a single cookie, instead of setting multiple cookies.

> **NOTE**
> RFC 6265 does not define the structure of cookie data.

Using the **CookieHeaderValue** class, you can pass a list of name-value pairs for the cookie data. These name-value pairs are encoded as URL-encoded form data in the Set-Cookie header:

```
var resp = new HttpResponseMessage();

var nv = new NameValueCollection();
nv["sid"] = "12345";
nv["token"] = "abcdef";
nv["theme"] = "dark blue";
var cookie = new CookieHeaderValue("session", nv);

resp.Headers.AddCookies(new CookieHeaderValue[] { cookie });
```

The previous code produces the following Set-Cookie header:

```
Set-Cookie: session=sid=12345&token=abcdef&theme=dark+blue;
```

The **CookieState** class provides an indexer method to read the sub-values from a cookie in the request message:

```
string sessionId = "";
string sessionToken = "";
string theme = "";

CookieHeaderValue cookie = Request.Headers.GetCookies("session").FirstOrDefault();
if (cookie != null)
{
    CookieState cookieState = cookie["session"];

    sessionId = cookieState["sid"];
    sessionToken = cookieState["token"];
    theme = cookieState["theme"];
}
```

Example: Set and Retrieve Cookies in a Message Handler

The previous examples showed how to use cookies from within a Web API controller. Another option is to use message handlers. Message handlers are invoked earlier in the pipeline than controllers. A message handler can read cookies from the request before the request reaches the controller, or add cookies to the response after the controller generates the response.

The following code shows a message handler for creating session IDs. The session ID is stored in a cookie. The handler checks the request for the session cookie. If the request does not include the cookie, the handler generates a new session ID. In either case, the handler stores the session ID in the **HttpRequestMessage.Properties**

property bag. It also adds the session cookie to the HTTP response.

This implementation does not validate that the session ID from the client was actually issued by the server. Don't use it as a form of authentication! The point of the example is to show HTTP cookie management.

```
using System;
using System.Linq;
using System.Net;
using System.Net.Http;
using System.Net.Http.Headers;
using System.Threading;
using System.Threading.Tasks;
using System.Web.Http;

public class SessionIdHandler : DelegatingHandler
{
    public static string SessionIdToken = "session-id";

    async protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        string sessionId;

        // Try to get the session ID from the request; otherwise create a new ID.
        var cookie = request.Headers.GetCookies(SessionIdToken).FirstOrDefault();
        if (cookie == null)
        {
            sessionId = Guid.NewGuid().ToString();
        }
        else
        {
            sessionId = cookie[SessionIdToken].Value;
            try
            {
                Guid guid = Guid.Parse(sessionId);
            }
            catch (FormatException)
            {
                // Bad session ID. Create a new one.
                sessionId = Guid.NewGuid().ToString();
            }
        }

        // Store the session ID in the request property bag.
        request.Properties[SessionIdToken] = sessionId;

        // Continue processing the HTTP request.
        HttpResponseMessage response = await base.SendAsync(request, cancellationToken);

        // Set the session ID as a cookie in the response message.
        response.Headers.AddCookies(new CookieHeaderValue[] {
            new CookieHeaderValue(SessionIdToken, sessionId)
        });

        return response;
    }
}
```

A controller can get the session ID from the **HttpRequestMessage.Properties** property bag.

```
public HttpResponseMessage Get()
{
    string sessionId = Request.Properties[SessionIdHandler.SessionIdToken] as string;

    return new HttpResponseMessage()
    {
        Content = new StringContent("Your session ID = " + sessionId)
    };
}
```

ASP.NET Web API Releases

What's New in ASP.NET Web API OData 5.3

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

This topic describes what's new for ASP.NET Web API OData 5.3.

- Download
- Documentation
- OData Core Libraries
- New Features
- Known Issues and Breaking Changes
- Bug Fixes
- ASP.NET Web API OData 5.3.1

Download

The runtime features are released as NuGet packages on the NuGet gallery. You can install or update to the released NuGet packages by using the NuGet Package Manager Console:

```
Install-Package Microsoft.AspNet.OData -Version 5.3.0
Install-Package Microsoft.AspNet.WebApi.OData -Version 5.3.0
```

Documentation

You can find tutorials and other documentation about ASP.NET Web API OData at the ASP.NET web site.

OData Core Libraries

For OData v4, Web API now uses ODataLib version 6.5.0

New Features in ASP.NET Web API OData 5.3

Support for $levels in $expand

You can use the $levels query option in $expand queries. For example:

```
http://example.com/Employees?$expand=Manager($levels=2)
```

This query is equivalent to:

```
http://example.com/Employees?$expand=Manager($expand=Manager))
```

Support for Open Entity Types

An *open type* is a structured type that contains dynamic properties, in addition to any properties that are declared in the type definition. Open types let you add flexibility to your data models. For more information, see xxxx.

Support for dynamic collection properties in open types

Previously, a dynamic property had to be a single value. In 5.3, dynamic properties can have collection values. For

example, in the following JSON payload, the `Emails` property is a dynamic property and is of collection of string type:

```
{
   "Id": 1,
   "Name": "Ben",
   "Emails@odata.type": "#Collection(Edm.String)",
   "Emails": [
      "a@a.com",
      "b@b.com"
   ]
}
```

Support for inheritance for complex types

Now complex types can inherit from a base type. For example, an OData service could define the following complex types:

```
public abstract class Shape
{
    public bool HasBorder { get; set; }
}

public class Point
{
    public int X { get; set; }
    public int Y { get; set; }
}

public class Circle : Shape
{
    public Point Center { get; set; }
    public int Radius { get; set; }

    public override string ToString()
    {
        return "{" + Center.X + "," + Center.Y + "," + Radius + "}";
    }
}

public class Polygon : Shape
{
    public IList<Point> Vertexes { get; set; }
    public Polygon()
    {
        Vertexes = new List<Point>();
    }
}
```

Here is the EDM for this example:

```
<?xml version="1.0" encoding="utf-8"?>
<edmx:Edmx Version="4.0" xmlns:edmx="http://docs.oasis-open.org/odata/ns/edmx">
  <edmx:DataServices>
    <Schema Namespace="ODataComplexTypeInheritanceSample" xmlns="http://docs.oasis-open.org/odata/ns/edm">
      <ComplexType Name="Shape" Abstract="true">
        <Property Name="HasBorder" Type="Edm.Boolean" Nullable="false" />
      </ComplexType>
      <ComplexType Name="Polygon" BaseType="ODataComplexTypeInheritanceSample.Shape">
        <Property Name="Vertexes" Type="Collection(ODataComplexTypeInheritanceSample.Point)" />
      </ComplexType>
      <ComplexType Name="Point">
        <Property Name="X" Type="Edm.Int32" Nullable="false" />
        <Property Name="Y" Type="Edm.Int32" Nullable="false" />
      </ComplexType>
      <ComplexType Name="Circle" BaseType="ODataComplexTypeInheritanceSample.Shape">
        <Property Name="Center" Type="ODataComplexTypeInheritanceSample.Point" />
        <Property Name="Radius" Type="Edm.Int32" Nullable="false" />
      </ComplexType>
      <EntityContainer Name="Container">
      </EntityContainer>
    </Schema>
  </edmx:DataServices>
</edmx:Edmx>
```

For more information, see OData Complex Type Inheritance Sample.

Known Issues and Breaking Changes

This section describes known issues and breaking changes in the ASP.NET Web API OData 5.3.

OData v4

Query Options

Issue: Using nested $expand with $levels=max results in an incorrect expansion depth.

For example, given the following request:

```
~/Entities(6)?$expand=P($levels=2;$expand=D($levels=max))
```

If `MaxExpansionDepth` is 5, this query would result in an expansion depth of 6.

Bug Fixes and Minor Feature Updates

This release also includes several bug fixes and minor feature updates. You can find the complete list here:

- Bug fixes

ASP.NET Web API OData 5.3.1

In this release we made a bug fix to some of the AllowedFunctions enums. This release doesn't have any other bug fixes or new features.

What's New in ASP.NET Web API 2.2

4/10/2020 • 6 minutes to read • Edit Online

by Microsoft

This topic describes what's new for ASP.NET Web API 2.2.

- Download
- Documentation
- New Features in ASP.NET Web API 2.2
  - OData v4
  - Attribute Routing Improvements
  - Web API Client support for Windows Phone 8.1
- Known Issues and Breaking Changes
- Bug Fixes
- Microsoft.AspNet.OData 5.2.1
- Microsoft.AspNet.WebAPI 5.2.2
- Microsoft.AspNet.WebAPI 5.2.3 Beta

Download

The runtime features are released as NuGet packages on the NuGet gallery. All the runtime packages follow the Semantic Versioning specification. The latest ASP.NET Web API 2.2 package has the following version: "5.2.0". You can install or update these packages through NuGet. The release also includes corresponding localized packages on NuGet.

You can install or update to the released NuGet packages by using the NuGet Package Manager Console:

```
Install-Package Microsoft.AspNet.WebApi -Version 5.2.0
```

Documentation

Tutorials and other information about ASP.NET Web API 2.2 are available from the ASP.NET web site (https://www.asp.net/web-api).

New Features in ASP.NET Web API 2.2

OData v4

This release adds support for the OData v4 protocol. For more information, see the Web API OData v4 documentation.

Here are some of the key features and changes for OData v4:

- Support for aliasing properties in OData model
- Support for ComplexTypeAttribute, AssociationAttribute, TimesTampAttribute and ConcurrencyCheckAttribute in ODataConventionModelBuilder

- Provide ability to supply friendly Title for actions
- Integrate with ODL UriParser
- Support for enum, containment and singleton
- Support cast for primitive types
- Added OData function support
- Support parameter aliases for function calls
- Support camel case naming convention in model
- Support for cast() in $filter
- Support for open complex type
- Removed EntitySetController and AsyncEntitySetController
- Changed $link to $ref
- Added Attribute routing support
- Uses OData Core Libraries 6.4.0

Attribute Routing Improvements

Attribute Routing now provides an extensibility point called IDirectRouteProvider, which allows full control over how attribute routes are discovered and configured. An IDirectRouteProvider is responsible for providing a list of actions and controllers along with associated route information to specify exactly what routing configuration is desired for those actions. An IDirectRouteProvider implementation may be specified when calling MapAttributes/MapHttpAttributeRoutes.

Customizing IDirectRouteProvider will be easiest by extending our default implementation, DefaultDirectRouteProvider. This class provides separate overridable virtual methods to change the logic for discovering attributes, creating route entries, and discovering route prefix and area prefix.

Following are some examples on what you could do with this new extensibility point:

1. Support inheritance of Route attributes

   Example:

   Here a request like "/api/values/10" would successfully return "Success:10"

   ```
   public class BaseController : ApiController
   {
       [Route("{id:int}")]
       public string Get(int id)
       {
           return "Success:" + id;
       }
   }
   [RoutePrefix("api/values")]
   public class ValuesController : BaseController
   {
   }

   config.MapHttpAttributeRoutes(new CustomDirectRouteProvider());
   public class CustomDirectRouteProvider : DefaultDirectRouteProvider
   {
       protected override IReadOnlyList<IDirectRouteFactory>
       GetActionRouteFactories(HttpActionDescriptor actionDescriptor)
       {
           return actionDescriptor.GetCustomAttributes<IDirectRouteFactory>
           (inherit: true);
       }
   }
   ```

2. Provide a default route name for your attribute routes by following some convention you like. By default,

attribute routing doesn't automatically create names for attribute routes.

3. Modify attribute routes' route template at one central place before they end up in the route table.

Web API Client Support for Windows Phone 8.1

You can now use the Web API Client NuGet package to implement your Web API client logic when targeting Windows Phone 8.1 or from within a Universal App.

Known Issues and Breaking Changes

This section describes known issues and breaking changes in the ASP.NET Web API 2.2.

OData v4

Model builder

Issue: Overloaded Functions could not be exposed as FunctionImport

If there are 2 overloaded functions and they are also FunctionImport as shown below then requesting ~/GetAllConventionCustomers(CustomerName={customerName}) results in System.InvalidOperationException.

```
<Function Name="GetAllConventionCustomers"
ReturnType="Collection(WebStack.QA.Test.OData.UnboundOperation.ConventionCustomer)"
IsComposable="true" />
<Function Name="GetAllConventionCustomers"
ReturnType="Collection(WebStack.QA.Test.OData.UnboundOperation.ConventionCustomer)"
IsComposable="true">
<Parameter Name="CustomerName" Type="Edm.String" FixedLength="false"
Unicode="false" />
</Function>
...
<FunctionImport Name="GetAllConventionCustomers"
Function="WebStack.QA.Test.OData.UnboundOperation.GetAllConventionCustomers"
EntitySet="ConventionCustomers" IncludeInServiceDocument="true" />
```

Workaround: The workaround for this issue is to add both the function overloads as FunctionImports.

OData Routing

String literals that include the URL encoded slash (%2F), and backslash(%5C) cause a 404 error when they are used in the OData resource paths.

For example, string literals can be used in the OData resource paths as parameters of functions or key values of entity sets.

/Employees/Total.GetCount(Name='Name%2F')

/Employees('Name%5C')

When services receive such requests the hosts will un-escape those escape sequences before passing them to the Web API runtime. This protects against attacks like the following:

```
http://www.contoso.com/..%2F..%2F/Windows/System32/cmd.exe?/c+dir+c:
```

This causes the Web API OData stack to return a 404 error (Not Found). To prevent this error, your client should use the double escape sequences for slash (%252F) and backslash (%255C). This does not happen for query strings such as /Employees?$filter=Name eq 'Name%2F'

Note un-escaped slashes ('/') and backslashes ('') are not legal in OData resource path string literals. Slashes should appear only as path separators and backslashes should not appear in the OData resource path at all. (Both are usable in some portions of an OData query string.)

Workaround: You could override the Parse method of DefaultODataPathHandler to escape the slash and backslash

in string literals before actually parsing them. You can find a sample of this approach here.

OData v3

[Queryable]

The [Queryable] attribute is deprecated. New OData v3 applications should use **System.Web.Http.OData.EnableQueryAttribute**.

The **ODataHttpConfigurationExtensions.EnableQuerySupport** extension method now adds an **EnableQueryAttribute** to the global filter collection. If any controllers have the **[Queryable]** attribute, calling `config.EnableQuerySupport()` will cause the **[Queryable]** attribute to fail

The recommended way to resolve this issue is to replace all instances of **QueryableAttribute** with **System.Web.Http.OData.EnableQueryAttribute**.

An alternative workaround is to use the following code in your Web API configuration:

```
config.EnableQuerySupport(new QueryableAttribute());
```

Attribute Routing

Issue: Model binding of complex type which is decorated with FromUri attribute behaves differently when using Attribute Routing.

Following link is tracking the issue and also has details about a workaround.
http://aspnetwebstack.codeplex.com/workitem/1944

Issue: Scaffolding MVC/Web API into a project with 5.2.0 packages results in 5.1.2 packages for ones that don't already exist in the project

Updating NuGet packages for ASP.NET MVC 5.2 does not update the Visual Studio tools such as ASP.NET scaffolding or the ASP.NET Web Application project template. They use the previous version of the ASP.NET runtime packages (e.g. 5.1.2 in Update 2). As a result, the ASP.NET scaffolding will install the previous version (e.g. 5.1.2 in Update 2) of the required packages, if they are not already available in your projects. However, the ASP.NET scaffolding in Visual Studio 2013 RTM or Update 1 does not overwrite the latest packages in your projects. If you use ASP.NET scaffolding after updating the packages of your projects to Web API 2.2 or ASP.NET MVC 5.2, make sure the versions of Web API and ASP.NET MVC are consistent.

Bug Fixes and Minor Feature Updates

This release also includes several bug fixes and minor feature updates. You can find the complete list here:

- 5.2 package

Microsoft.AspNet.OData 5.2.1

The Microsoft.AspNet.OData 5.2.1 package contains NuGet dependency updates but no bug fixes. With this update, there is no longer a strict dependency on Microsoft.OData.Core 6.4.0, but one can upgrade to any version between 6.4.0 and 7.0.0.

Microsoft.AspNet.WebAPI 5.2.2

In this release we have made a dependency change for `Json.Net 6.0.4`. For more information on what is new in this release of `Json.NET`, see Json.NET 6.0 Release 4 - JSON Merge, Dependency Injection. This release doesn't have any other new features or bug fixes in Web API. We have subsequently updated all other dependent packages we own to depend on this new version of Web API.

Microsoft.AspNet.WebAPI 5.2.3 Beta

You can read about the release here. This release contains only bug fixes. You can use this query to see the list of issues fixed in this release.

What's New in ASP.NET Web API 2.1

4/10/2020 • 5 minutes to read • Edit Online

by Microsoft

This topic describes what's new for ASP.NET Web API 2.1.

- Download
- Documentation
- New Features in ASP.NET Web API 2.1
  - Global Error Handling
  - Attribute Routing Improvements
  - Help Page Improvements
  - IgnoreRoute Support
  - BSON Media-Type Formatter
  - Better Support for Async Filters
  - Query Parsing for the Client Formatting Library
- Known Issues and Breaking Changes
- Bug Fixes

Download

The runtime features are released as NuGet packages on the NuGet gallery. All the runtime packages follow the Semantic Versioning specification. The latest ASP.NET Web API 2.1 RTM package has the following version: "5.1.2". You can install or update these packages through NuGet. The release also includes corresponding localized packages on NuGet.

You can install or update to the released NuGet packages by using the NuGet Package Manager Console:

```
Install-Package Microsoft.AspNet.WebApi -Version 5.1.2
```

Documentation

Tutorials and other information about ASP.NET Web API 2.1 RTM are available from the ASP.NET web site (https://www.asp.net/web-api).

New Features in ASP.NET Web API 2.1

Global Error Handling

All unhandled exceptions can now be logged through one central mechanism, and the behavior for unhandled exceptions can be customized.

The framework supports multiple exception loggers, which all see the unhandled exception and information about the context in which it occurred, such as the request being processed at the time.

For example, the following code uses System.Diagnostics.TraceSource to log all unhandled exceptions:

```
public class TraceSourceExceptionLogger : ExceptionLogger
{
    private readonly TraceSource _traceSource;

    public TraceSourceExceptionLogger(TraceSource traceSource)
    {
        _traceSource = traceSource;
    }

    public override void Log(ExceptionLoggerContext context)
    {
        _traceSource.TraceEvent(TraceEventType.Error, 1,
            "Unhandled exception processing {0} for {1}: {2}",
            context.Request.Method,
            context.Request.RequestUri,
            context.Exception);
    }
}

config.Services.Add(typeof(IExceptionLogger),
    new TraceSourceExceptionLogger(new
    TraceSource("MyTraceSource", SourceLevels.All)));
```

You can also replace the default exception handler, so that you can fully customize the HTTP response message that is sent when an unhandled exception occurs.

We have provided a sample that logs all unhandled exceptions via the popular ELMAH framework.

Attribute Routing Improvements

Attribute routing now supports constraints, enabling versioning and header-based route selection. Also, many aspects of attribute routes are now customizable via the **IDirectRouteFactory** interface and **RouteFactoryAttribute** class. The route prefix is now extensible via the **IRoutePrefix** interface and **RoutePrefixAttribute** class.

We have provided a sample that uses constraints to dynamically filter controllers by an 'api-version' HTTP header.

Help Page Improvements

Web API 2.1 includes the following enhancements to API Help Pages:

- Documentation of individual properties of parameters or return types of actions.
- Documentation of data model annotations.

The UI design of the help pages was also updated, to accommodate these changes.

IgnoreRoute Support

Web API 2.1 supports ignoring URL patterns in Web API routing, through a set of **IgnoreRoute** extension methods on **HttpRouteCollection**. These methods cause Web API to ignore any URLs that match a specified template, and allow the host to apply additional processing if appropriate.

The following example ignores URIs that start with a "content" segment:

```
routes.IgnoreRoute("IgnoreContent", "content/{*paths}");
routes.MapHttpRoute("Default", "{controller}/{id}");
```

BSON Media-Type Formatter

Web API now supports the BSON wire format, both on the client and on the server.

To enable BSON on the server side, add the **BsonMediaTypeFormatter** to the formatters collection:

```
config.Formatters.Add(new BsonMediaTypeFormatter());
```

Here is how a .NET client can consume BSON format:

```
// Add Accept header.
client.DefaultRequestHeaders.Accept.Add(
    new MediaTypeWithQualityHeaderValue("application/bson"));

// POST data in BSON format.
HttpResponseMessage response = await client.PostAsync<MyData>("api/MyData", data, new
BsonMediaTypeFormatter());

// GET data in BSON format.
data = await response.Content.ReadAsAsync<MyData>(new MediaTypeFormatter[] {
  new BsonMediaTypeFormatter() });
```

We have provided a sample that shows both the client and server side.

For more information, see BSON Support in Web API 2.1

Better Support for Async Filters

Web API now supports an easy way to create filters that execute asynchronously. This feature is useful is your filter needs to perform an async action, such as access a database. Previously, to create an async filter, you had to implement the filter interface yourself, because the filter base classes only exposed synchronous methods. Now you can override the virtual `On*Async` methods of the filter base class.

For example:

```
public class AsyncLoggingFilter : ActionFilterAttribute
{
    public override async Task OnActionExecutingAsync(HttpActionContext actionContext, CancellationToken
cancellationToken)
    {
        await Trace.WriteAsync("Executing action named {0} for request {1}.",
            actionContext.ActionDescriptor.ActionName,
            actionContext.Request.GetCorrelationId());
    }
}
```

The **AuthorizationFilterAttribute**, **ActionFilterAttribute**, and **ExceptionFilterAttribute** classes all support async in Web API 2.1.

Query Parsing for the Client Formatting Library

Previously, **System.Net.Http.Formatting** supported parsing and updating URI queries for server-side code, but the equivalent portable library was missing this feature. In Web API 2.1, a client application can now easily parse and update a query string.

The following examples show how to parse, modify, and generate URI queries. (The examples show a console application for simplicity.)

```
// Query parsing
HttpValueCollection collection = new Uri("http://api/something?catId=3&catId=4&dogId=1,2").ParseQueryString();

Console.WriteLine(collection["catId"]); // output: 3,4
Console.WriteLine(collection["dogId"]); // output: 1,2

// Modify the query
collection.Add("dogId", "7");

// Index into the values
Console.WriteLine(collection["catId"]); // output: 3,4
Console.WriteLine(collection["dogId"]); // output: 1,2,7

// Recreate the query string
Console.WriteLine(collection.ToString()); // output: catId=3&catId=4&dogId=1%2C2&dogId=7

// Query generation
HttpValueCollection newCollection = new HttpValueCollection();

newCollection.Add("catId", "1");
newCollection.Add("dogId", "7");

// Index into the values
Console.WriteLine(newCollection["catId"]); // output: 1
Console.WriteLine(newCollection["dogId"]); // output: 7

// Create the query string
Console.WriteLine(newCollection.ToString()); // catId=1&dogId=7
```

Known Issues and Breaking Changes

This section describes known issues and breaking changes in the ASP.NET Web API 2.1 RTM.

Attribute Routing

Ambiguities in attribute routing matches now report an error rather than choosing the first match.

Attribute routes are prohibited from using the *{controller}* parameter, and from using the *{action}* parameter on routes placed on actions. These parameters would very likely cause ambiguities.

Scaffolding MVC/Web API into a project with 5.1 packages results in 5.0 packages for ones that don't already exist in the project

Updating NuGet packages for ASP.NET Web API 2.1 RTM does not update the Visual Studio tools, such as ASP.NET scaffolding or the ASP.NET Web Application project template. They use the previous version of the ASP.NET runtime packages (5.0.0.0). As a result, the ASP.NET scaffolding will install the previous version (5.0.0.0) of the required packages, if they are not already available in your projects. However, the ASP.NET scaffolding in Visual Studio 2013 RTM or Update 1 does not overwrite the latest packages in your projects.

If you use ASP.NET scaffolding after updating the packages to Web API 2.1 or ASP.NET MVC 5.1, make sure the versions of Web API and MVC are consistent.

Type Renames

Some of the types used for attribute routing extensibility were renamed from the RC to the 2.1 RTM.

OLD TYPE NAME (2.1 RC)	NEW TYPE NAME (2.1 RTM)
IDirectRouteProvider	IDirectRouteFactory
RouteProviderAttribute	RouteFactoryAttribute

OLD TYPE NAME (2.1 RC)	NEW TYPE NAME (2.1 RTM)
DirectRouteProviderContext	DirectRouteFactoryContext

Exception filters do not unwrap aggregate exceptions thrown in async actions

Previously, if an async action threw an **AggregateException**, an exception filter would unwrap the exception, and **OnException** would get the base exception. In 2.1, the exception filter does not unwrap it, and **OnException** gets the original **AggregateException**.

Bug Fixes

This release also includes several bug fixes. You can find the complete list here:

- 5.1.0 package
- 5.1.1 package

The 5.1.2 package contains IntelliSense updates but no bug fixes.

Enabling CRUD Operations in ASP.NET Web API 1

2/20/2020 • 9 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

> This tutorial shows how to support CRUD operations in an HTTP service using ASP.NET Web API for ASP.NET 4.x.
>
> ## Software versions used in the tutorial
>
> - Visual Studio 2012
> - Web API 1 (also works with Web API 2)

CRUD stands for "Create, Read, Update, and Delete," which are the four basic database operations. Many HTTP services also model CRUD operations through REST or REST-like APIs.

In this tutorial, you will build a very simple web API to manage a list of products. Each product will contain a name, price, and category (such as "toys" or "hardware"), plus a product ID.

The products API will expose following methods.

ACTION	HTTP METHOD	RELATIVE URI
Get a list of all products	GET	/api/products
Get a product by ID	GET	/api/products/*id*
Get a product by category	GET	/api/products?category=*category*
Create a new product	POST	/api/products
Update a product	PUT	/api/products/*id*
Delete a product	DELETE	/api/products/*id*

Notice that some of the URIs include the product ID in path. For example, to get the product whose ID is 28, the client sends a GET request for `http://hostname/api/products/28`.

Resources

The products API defines URIs for two resource types:

RESOURCE	URI
The list of all the products.	/api/products
An individual product.	/api/products/*id*

Methods

The four main HTTP methods (GET, PUT, POST, and DELETE) can be mapped to CRUD operations as follows:

- GET retrieves the representation of the resource at a specified URI. GET should have no side effects on the server.
- PUT updates a resource at a specified URI. PUT can also be used to create a new resource at a specified URI, if the server allows clients to specify new URIs. For this tutorial, the API will not support creation through PUT.
- POST creates a new resource. The server assigns the URI for the new object and returns this URI as part of the response message.
- DELETE deletes a resource at a specified URI.

Note: The PUT method replaces the entire product entity. That is, the client is expected to send a complete representation of the updated product. If you want to support partial updates, the PATCH method is preferred. This tutorial does not implement PATCH.

Create a New Web API Project

Start by running Visual Studio and select **New Project** from the **Start** page. Or, from the **File** menu, select **New** and then **Project**.

In the **Templates** pane, select **Installed Templates** and expand the **Visual C#** node. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET MVC 4 Web Application**. Name the project "ProductStore" and click **OK**.

In the **New ASP.NET MVC 4 Project** dialog, select **Web API** and click **OK**.

Adding a Model

A *model* is an object that represents the data in your application. In ASP.NET Web API, you can use strongly typed CLR objects as models, and they will automatically be serialized to XML or JSON for the client.

For the ProductStore API, our data consists of products, so we'll create a new class named `Product`.

If Solution Explorer is not already visible, click the **View** menu and select **Solution Explorer**. In Solution Explorer, right-click the **Models** folder. From the context menu, select **Add**, then select **Class**. Name the class "Product".

Add the following properties to the `Product` class.

```
namespace ProductStore.Models
{
    public class Product
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public string Category { get; set; }
        public decimal Price { get; set; }
    }
}
```

Adding a Repository

We need to store a collection of products. It's a good idea to separate the collection from our service implementation. That way, we can change the backing store without rewriting the service class. This type of design is called the *repository* pattern. Start by defining a generic interface for the repository.

In Solution Explorer, right-click the **Models** folder. Select **Add**, then select **New Item**.

In the **Templates** pane, select **Installed Templates** and expand the C# node. Under C#, select **Code**. In the list of code templates, select **Interface**. Name the interface "IProductRepository".

Add the following implementation:

```
namespace ProductStore.Models
{
    public interface IProductRepository
    {
        IEnumerable<Product> GetAll();
        Product Get(int id);
        Product Add(Product item);
        void Remove(int id);
        bool Update(Product item);
    }
}
```

Now add another class to the Models folder, named "ProductRepository." This class will implement the `IProductRepository` interface. Add the following implementation:

```
namespace ProductStore.Models
{
    public class ProductRepository : IProductRepository
    {
        private List<Product> products = new List<Product>();
        private int _nextId = 1;

        public ProductRepository()
        {
            Add(new Product { Name = "Tomato soup", Category = "Groceries", Price = 1.39M });
            Add(new Product { Name = "Yo-yo", Category = "Toys", Price = 3.75M });
            Add(new Product { Name = "Hammer", Category = "Hardware", Price = 16.99M });
        }

        public IEnumerable<Product> GetAll()
        {
            return products;
        }

        public Product Get(int id)
        {
            return products.Find(p => p.Id == id);
        }

        public Product Add(Product item)
        {
            if (item == null)
            {
                throw new ArgumentNullException("item");
            }
            item.Id = _nextId++;
            products.Add(item);
            return item;
        }

        public void Remove(int id)
        {
            products.RemoveAll(p => p.Id == id);
        }

        public bool Update(Product item)
        {
            if (item == null)
            {
                throw new ArgumentNullException("item");
            }
            int index = products.FindIndex(p => p.Id == item.Id);
            if (index == -1)
            {
                return false;
            }
            products.RemoveAt(index);
            products.Add(item);
            return true;
        }
    }
}
```

The repository keeps the list in local memory. This is OK for a tutorial, but in a real application, you would store the data externally, either a database or in cloud storage. The repository pattern will make it easier to change the implementation later.

Adding a Web API Controller

If you have worked with ASP.NET MVC, then you are already familiar with controllers. In ASP.NET Web API, a

controller is a class that handles HTTP requests from the client. The New Project wizard created two controllers for you when it created the project. To see them, expand the Controllers folder in Solution Explorer.

- HomeController is a traditional ASP.NET MVC controller. It is responsible for serving HTML pages for the site, and is not directly related to our web API.
- ValuesController is an example WebAPI controller.

Go ahead and delete ValuesController, by right-clicking the file in Solution Explorer and selecting **Delete.** Now add a new controller, as follows:

In **Solution Explorer**, right-click the Controllers folder. Select **Add** and then select **Controller**.

In the **Add Controller** wizard, name the controller "ProductsController". In the **Template** drop-down list, select **Empty API Controller**. Then click **Add**.

> **NOTE**
> It is not necessary to put your controllers into a folder named Controllers. The folder name is not important; it is simply a convenient way to organize your source files.

The **Add Controller** wizard will create a file named ProductsController.cs in the Controllers folder. If this file is not open already, double-click the file to open it. Add the following **using** statement:

```
using ProductStore.Models;
```

Add a field that holds an **IProductRepository** instance.

```
public class ProductsController : ApiController
{
    static readonly IProductRepository repository = new ProductRepository();
}
```

> **NOTE**
> Calling `new ProductRepository()` in the controller is not the best design, because it ties the controller to a particular implementation of `IProductRepository`. For a better approach, see Using the Web API Dependency Resolver.

Getting a Resource

The ProductStore API will expose several "read" actions as HTTP GET methods. Each action will correspond to a method in the `ProductsController` class.

ACTION	HTTP METHOD	RELATIVE URI
Get a list of all products	GET	/api/products

ACTION	HTTP METHOD	RELATIVE URI
Get a product by ID	GET	/api/products/*id*
Get a product by category	GET	/api/products?category=*category*

To get the list of all products, add this method to the `ProductsController` class:

```
public class ProductsController : ApiController
{
    public IEnumerable<Product> GetAllProducts()
    {
        return repository.GetAll();
    }
    // ....
}
```

The method name starts with "Get", so by convention it maps to GET requests. Also, because the method has no parameters, it maps to a URI that does not contain an *"id"* segment in the path.

To get a product by ID, add this method to the `ProductsController` class:

```
public Product GetProduct(int id)
{
    Product item = repository.Get(id);
    if (item == null)
    {
        throw new HttpResponseException(HttpStatusCode.NotFound);
    }
    return item;
}
```

This method name also starts with "Get", but the method has a parameter named *id*. This parameter is mapped to the "id" segment of the URI path. The ASP.NET Web API framework automatically converts the ID to the correct data type (**int**) for the parameter.

The GetProduct method throws an exception of type **HttpResponseException** if *id* is not valid. This exception will be translated by the framework into a 404 (Not Found) error.

Finally, add a method to find products by category:

```
public IEnumerable<Product> GetProductsByCategory(string category)
{
    return repository.GetAll().Where(
        p => string.Equals(p.Category, category, StringComparison.OrdinalIgnoreCase));
}
```

If the request URI has a query string, Web API tries to match the query parameters to parameters on the controller method. Therefore, a URI of the form "api/products?category=*category*" will map to this method.

Creating a Resource

Next, we'll add a method to the `ProductsController` class to create a new product. Here is a simple implementation of the method:

```
// Not the final implementation!
public Product PostProduct(Product item)
{
    item = repository.Add(item);
    return item;
}
```

Note two things about this method:

- The method name starts with "Post...". To create a new product, the client sends an HTTP POST request.
- The method takes a parameter of type Product. In Web API, parameters with complex types are deserialized from the request body. Therefore, we expect the client to send a serialized representation of a product object, in either XML or JSON format.

This implementation will work, but it is not quite complete. Ideally, we would like the HTTP response to include the following:

- **Response code:** By default, the Web API framework sets the response status code to 200 (OK). But according to the HTTP/1.1 protocol, when a POST request results in the creation of a resource, the server should reply with status 201 (Created).
- **Location:** When the server creates a resource, it should include the URI of the new resource in the Location header of the response.

ASP.NET Web API makes it easy to manipulate the HTTP response message. Here is the improved implementation:

```
public HttpResponseMessage PostProduct(Product item)
{
    item = repository.Add(item);
    var response = Request.CreateResponse<Product>(HttpStatusCode.Created, item);

    string uri = Url.Link("DefaultApi", new { id = item.Id });
    response.Headers.Location = new Uri(uri);
    return response;
}
```

Notice that the method return type is now **HttpResponseMessage**. By returning an **HttpResponseMessage** instead of a Product, we can control the details of the HTTP response message, including the status code and the Location header.

The **CreateResponse** method creates an **HttpResponseMessage** and automatically writes a serialized representation of the Product object into the body fo the response message.

> **NOTE**
>
> This example does not validate the `Product`. For information about model validation, see Model Validation in ASP.NET Web API.

Updating a Resource

Updating a product with PUT is straightforward:

```
public void PutProduct(int id, Product product)
{
    product.Id = id;
    if (!repository.Update(product))
    {
        throw new HttpResponseException(HttpStatusCode.NotFound);
    }
}
```

The method name starts with "Put...", so Web API matches it to PUT requests. The method takes two parameters, the product ID and the updated product. The *id* parameter is taken from the URI path, and the *product* parameter is deserialized from the request body. By default, the ASP.NET Web API framework takes simple parameter types from the route and complex types from the request body.

Deleting a Resource

To delete a resource, define a "Delete..." method.

```
public void DeleteProduct(int id)
{
    Product item = repository.Get(id);
    if (item == null)
    {
        throw new HttpResponseException(HttpStatusCode.NotFound);
    }

    repository.Remove(id);
}
```

If a DELETE request succeeds, it can return status 200 (OK) with an entity-body that describes the status; status 202 (Accepted) if the deletion is still pending; or status 204 (No Content) with no entity body. In this case, the `DeleteProduct` method has a `void` return type, so ASP.NET Web API automatically translates this into status code 204 (No Content).

Using ASP.NET Web API 1 with Entity Framework 5

2/20/2020 • 2 minutes to read • Edit Online

How to create a Web API 1 application that uses Entity Framework for database persistence.

- Overview and Creating the Project
- Creating the Domain Models
- Creating an Admin Controller
- Adding an Admin View
- Creating a Dynamic UI with Knockout.js
- Creating Product and Order Controllers

by Mike Wasson

Download Completed Project

Entity Framework is an object/relational mapping framework. It maps the domain objects in your code to entities in a relational database. For the most part, you do not have to worry about the database layer, because Entity Framework takes care of it for you. Your code manipulates the objects, and changes are persisted to a database.

About the Tutorial

In this tutorial, you will create a simple store application. There are two main parts to the application. Normal users can view products and create orders:

Administrators can create, delete, or edit products:

Skills You'll Learn

Here's what you'll learn:

- How to use Entity Framework with ASP.NET Web API.
- How to use knockout.js to create a dynamic client UI.
- How to use forms authentication with Web API to authenticate users.

Although this tutorial is self-contained, you might want to read the following tutorials first:

- Your First ASP.NET Web API
- Creating a Web API that Supports CRUD Operations

Some knowledge of ASP.NET MVC is also helpful.

Overview

At a high level, here is the architecture of the application:

- ASP.NET MVC generates the HTML pages for the client.
- ASP.NET Web API exposes CRUD operations on the data (products and orders).
- Entity Framework translates the C# models used by Web API into database entities.

The following diagram shows how the domain objects are represented at various layers of the application: The database layer, the object model, and finally the wire format, which is used to transmit data to the client via HTTP.

Create the Visual Studio Project

You can create the tutorial project using either Visual Web Developer Express or the full version of Visual Studio.

From the **Start** page, click **New Project**.

In the **Templates** pane, select **Installed Templates** and expand the **Visual C#** node. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET MVC 4 Web Application**. Name the project "ProductStore" and click **OK**.

In the **New ASP.NET MVC 4 Project** dialog, select **Internet Application** and click **OK**.

The "Internet Application" template creates an ASP.NET MVC application that supports forms authentication. If you run the application now, it already has some features:

- New users can register by clicking the "Register" link in the upper right corner.
- Registered users can log in by clicking the "Log in" link.

Membership information is persisted in a database that gets created automatically. For more information about forms authentication in ASP.NET MVC, see Walkthrough: Using Forms Authentication in ASP.NET MVC.

Update the CSS File

This step is cosmetic, but it will make the pages render like the earlier screen shots.

In Solution Explorer, expand the Content folder and open the file named Site.css. Add the following CSS styles:

```
.content {
    clear: both;
    width: 90%;
}

li {
    list-style-type: none;
}

#products li {
    width: 300px;
    background-color: #aaf;
    font-size: 1.5em;
    font-weight: bold;
    color: #ff0;
    margin: 0 0 5px 0;
    padding: 0 5px 0 5px;
}

.price  {
    float: right;
    color: #c00;
    font-size: 0.75em;
}

.details thead td {
    background-color: #CCCCCC;
    color: #333333;
}

.details td {
padding: 6px;
}

.details td.qty {
text-align: center;
}

#cart a {
color: Blue;
font-size: .75em;
}

#update-products li {
    padding: 5px;
    color: #666;
    border-style: dashed;
    border-width: 2px;
    border-color: #666;
}

#update-products li .item {
width: 120px;
display: inline-block;
text-align: right;
}
```

NEXT

Part 2: Creating the Domain Models

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

Add Models

There are three ways to approach Entity Framework:

- Database-first: You start with a database, and Entity Framework generates the code.
- Model-first: You start with a visual model, and Entity Framework generates both the database and code.
- Code-first: You start with code, and Entity Framework generates the database.

We are using the code-first approach, so we start by defining our domain objects as POCOs (plain-old CLR objects). With the code-first approach, domain objects don't need any extra code to support the database layer, such as transactions or persistence. (Specifically, they do not need to inherit from the EntityObject class.) You can still use data annotations to control how Entity Framework creates the database schema.

Because POCOs do not carry any extra properties that describe database state, they can easily be serialized to JSON or XML. However, that does not mean you should always expose your Entity Framework models directly to clients, as we'll see later in the tutorial.

We will create the following POCOs:

- Product
- Order
- OrderDetail

To create each class, right-click the Models folder in Solution Explorer. From the context menu, select **Add** and then select **Class.**

Add a `Product` class with the following implementation:

```
namespace ProductStore.Models
{
    using System.ComponentModel.DataAnnotations;

    public class Product
    {
        [ScaffoldColumn(false)]
        public int Id { get; set; }
        [Required]
        public string Name { get; set; }
        public decimal Price { get; set; }
        public decimal ActualCost { get; set; }
    }
}
```

By convention, Entity Framework uses the `Id` property as the primary key and maps it to an identity column in the database table. When you create a new `Product` instance, you won't set a value for `Id`, because the database generates the value.

The **ScaffoldColumn** attribute tells ASP.NET MVC to skip the `Id` property when generating an editor form. The **Required** attribute is used to validate the model. It specifies that the `Name` property must be a non-empty string.

Add the `Order` class:

```
namespace ProductStore.Models
{
    using System.Collections.Generic;
    using System.ComponentModel.DataAnnotations;

    public class Order
    {
        public int Id { get; set; }
        [Required]
        public string Customer { get; set; }

        // Navigation property
        public  ICollection<OrderDetail> OrderDetails { get; set; }
    }
}
```

Add the `OrderDetail` class:

```
namespace ProductStore.Models
{
    public class OrderDetail
    {
        public int Id { get; set; }
        public int Quantity { get; set; }
        public int OrderId { get; set; }
        public int ProductId { get; set; }

        // Navigation properties
        public Product Product { get; set; }
        public Order Order { get; set; }
    }
}
```

Foreign Key Relations

An order contains many order details, and each order detail refers to a single product. To represent these relations, the `OrderDetail` class defines properties named `OrderId` and `ProductId`. Entity Framework will infer that these properties represent foreign keys, and will add foreign-key constraints to the database.

The `Order` and `OrderDetail` classes also include "navigation" properties, which contain references to the related objects. Given an order, you can navigate to the products in the order by following the navigation properties.

Compile the project now. Entity Framework uses reflection to discover the properties of the models, so it requires a compiled assembly to create the database schema.

Configure the Media-Type Formatters

A media-type formatter is an object that serializes your data when Web API writes the HTTP response body. The built-in formatters support JSON and XML output. By default, both of these formatters serialize all objects by value.

Serialization by value creates a problem if an object graph contains circular references. That's exactly the case with the `Order` and `OrderDetail` classes, because each holds a reference to the other. The formatter will follow the references, writing each object by value, and go in circles. Therefore, we need to change the default behavior.

In Solution Explorer, expand the App_Start folder and open the file named WebApiConfig.cs. Add the following code to the `WebApiConfig` class:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        config.Routes.MapHttpRoute(
            name: "DefaultApi",
            routeTemplate: "api/{controller}/{id}",
            defaults: new { id = RouteParameter.Optional }
        );

        // New code:
        var json = config.Formatters.JsonFormatter;
        json.SerializerSettings.PreserveReferencesHandling =
            Newtonsoft.Json.PreserveReferencesHandling.Objects;

        config.Formatters.Remove(config.Formatters.XmlFormatter);
    }
}
```

This code sets the JSON formatter to preserve object references, and removes the XML formatter from the pipeline entirely. (You can configure the XML formatter to preserve object references, but it's a little more work, and we only need JSON for this application. For more information, see Handling Circular Object References.)

Part 3: Creating an Admin Controller

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

Add an Admin Controller

In this section, we'll add a Web API controller that supports CRUD (create, read, update, and delete) operations on products. The controller will use Entity Framework to communicate with the database layer. Only administrators will be able to use this controller. Customers will access the products through another controller.

In Solution Explorer, right-click the Controllers folder. Select **Add** and then **Controller**.

In the **Add Controller** dialog, name the controller `AdminController`. Under **Template**, select "API controller with read/write actions, using Entity Framework". Under **Model class**, select "Product (ProductStore.Models)". Under **Data Context**, select "<New Data Context>".

> **NOTE**
>
> If the **Model class** drop-down does not show any model classes, make sure you compiled the project. Entity Framework uses reflection, so it needs the compiled assembly.

Selecting "<New Data Context>" will open the **New Data Context** dialog. Name the data context `ProductStore.Models.OrdersContext`.

Click **OK** to dismiss the **New Data Context** dialog. In the **Add Controller** dialog, click **Add**.

Here's what got added to the project:

- A class named `OrdersContext` that derives from **DbContext**. This class provides the glue between the POCO models and the database.
- A Web API controller named `AdminController`. This controller supports CRUD operations on `Product` instances. It uses the `OrdersContext` class to communicate with Entity Framework.
- A new database connection string in the Web.config file.

Open the OrdersContext.cs file. Notice that the constructor specifies the name of the database connection string. This name refers to the connection string that was added to Web.config.

```
public OrdersContext() : base("name=OrdersContext")
```

Add the following properties to the `OrdersContext` class:

```
public DbSet<Order> Orders { get; set; }
public DbSet<OrderDetail> OrderDetails { get; set; }
```

A **DbSet** represents a set of entities that can be queried. Here is the complete listing for the `OrdersContext` class:

```
public class OrdersContext : DbContext
{
    public OrdersContext() : base("name=OrdersContext")
    {
    }

    public DbSet<Order> Orders { get; set; }
    public DbSet<OrderDetail> OrderDetails { get; set; }
    public DbSet<Product> Products { get; set; }
}
```

The `AdminController` class defines five methods that implement basic CRUD functionality. Each method corresponds to a URI that the client can invoke:

CONTROLLER METHOD	DESCRIPTION	URI	HTTP METHOD
GetProducts	Gets all products.	api/products	GET
GetProduct	Finds a product by ID.	api/products/*id*	GET

CONTROLLER METHOD	DESCRIPTION	URI	HTTP METHOD
PutProduct	Updates a product.	api/products/*id*	PUT
PostProduct	Creates a new product.	api/products	POST
DeleteProduct	Deletes a product.	api/products/*id*	DELETE

Each method calls into `OrdersContext` to query the database. The methods that modify the collection (PUT, POST, and DELETE) call `db.SaveChanges` to persist the changes to the database. Controllers are created per HTTP request and then disposed, so it is necessary to persist changes before a method returns.

Add a Database Initializer

Entity Framework has a nice feature that lets you populate the database on startup, and automatically recreate the database whenever the models change. This feature is useful during development, because you always have some test data, even if you change the models.

In Solution Explorer, right-click the Models folder and create a new class named `OrdersContextInitializer`. Paste in the following implementation:

```
namespace ProductStore.Models
{
    using System;
    using System.Collections.Generic;
    using System.Data.Entity;

    public class OrdersContextInitializer : DropCreateDatabaseIfModelChanges<OrdersContext>
    {
        protected override void Seed(OrdersContext context)
        {
            var products = new List<Product>()
            {
                new Product() { Name = "Tomato Soup", Price = 1.39M, ActualCost = .99M },
                new Product() { Name = "Hammer", Price = 16.99M, ActualCost = 10 },
                new Product() { Name = "Yo yo", Price = 6.99M, ActualCost = 2.05M }
            };

            products.ForEach(p => context.Products.Add(p));
            context.SaveChanges();

            var order = new Order() { Customer = "Bob" };
            var od = new List<OrderDetail>()
            {
                new OrderDetail() { Product = products[0], Quantity = 2, Order = order},
                new OrderDetail() { Product = products[1], Quantity = 4, Order = order }
            };
            context.Orders.Add(order);
            od.ForEach(o => context.OrderDetails.Add(o));

            context.SaveChanges();
        }
    }
}
```

By inheriting from the **DropCreateDatabaseIfModelChanges** class, we are telling Entity Framework to drop the database whenever we modify the model classes. When Entity Framework creates (or recreates) the database, it calls the **Seed** method to populate the tables. We use the **Seed** method to add some example products plus an

example order.

This feature is great for testing, but don't use the **DropCreateDatabaseIfModelChanges** class in production,, because you could lose your data if someone changes a model class.

Next, open Global.asax and add the following code to the **Application_Start** method:

```
System.Data.Entity.Database.SetInitializer(
    new ProductStore.Models.OrdersContextInitializer());
```

Send a Request to the Controller

At this point, we haven't written any client code, but you can invoke the web API using a web browser or an HTTP debugging tool such as Fiddler. In Visual Studio, press F5 to start debugging. Your web browser will open to `http://localhost:*portnum*/`, where *portnum* is some port number.

Send an HTTP request to "`http://localhost:*portnum*/api/admin`. The first request may be slow to complete, because Entity Framework needs to create and seed the database. The response should something similar to the following:

```
HTTP/1.1 200 OK
Server: ASP.NET Development Server/10.0.0.0
Date: Mon, 18 Jun 2012 04:30:33 GMT
X-AspNet-Version: 4.0.30319
Cache-Control: no-cache
Pragma: no-cache
Expires: -1
Content-Type: application/json; charset=utf-8
Content-Length: 175
Connection: Close

[{"Id":1,"Name":"Tomato Soup","Price":1.39,"ActualCost":0.99},{"Id":2,"Name":"Hammer",
"Price":16.99,"ActualCost":10.00},{"Id":3,"Name":"Yo yo","Price":6.99,"ActualCost":
2.05}]
```

Part 4: Adding an Admin View

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

Add an Admin View

Now we'll turn to the client side, and add a page that can consume data from the Admin controller. The page will allow users to create, edit, or delete products, by sending AJAX requests to the controller.

In Solution Explorer, expand the Controllers folder and open the file named HomeController.cs. This file contains an MVC controller. Add a method named `Admin`:

```
public ActionResult Admin()
{
    string apiUri= Url.HttpRouteUrl("DefaultApi", new { controller = "admin", });
    ViewBag.ApiUrl = new Uri(Request.Url, apiUri).AbsoluteUri.ToString();

    return View();
}
```

The **HttpRouteUrl** method creates the URI to the web API, and we store this in the view bag for later.

Next, position the text cursor within the `Admin` action method, then right-click and select **Add View**. This will bring up the **Add View** dialog.

In the **Add View** dialog, name the view "Admin". Select the check box labeled **Create a strongly-typed view**. Under **Model Class**, select "Product (ProductStore.Models)". Leave all the other options as their default values.

Clicking **Add** adds a file named Admin.cshtml under Views/Home. Open this file and add the following HTML. This HTML defines the structure of the page, but no functionality is wired up yet.

```
<div class="content">
    <div class="float-left">
        <ul id="update-products">
            <li>
                <div><div class="item">Product ID</div><span></span></div>
                <div><div class="item">Name</div> <input type="text" /></div>
                <div><div class="item">Price ($)</div> <input type="text" /></div>
                <div><div class="item">Actual Cost ($)</div> <input type="text" /></div>
                <div>
                    <input type="button" value="Update" />
                    <input type="button" value="Delete Item" />
                </div>
         </li>
        </ul>
    </div>

    <div class="float-right">
    <h2>Add New Product</h2>
    <form id="product">
        @Html.ValidationSummary(true)
        <fieldset>
            <legend>Contact</legend>
            @Html.EditorForModel()
            <p>
                <input type="submit" value="Save" />
            </p>
        </fieldset>
    </form>
    </div>
</div>
```

Create a Link to the Admin Page

In Solution Explorer, expand the Views folder and then expand the Shared folder. Open the file named _Layout.cshtml. Locate the **ul** element with id = "menu", and an action link for the Admin view:

```
<li>@Html.ActionLink("Admin", "Admin", "Home")</li>
```

NOTE

In the sample project, I made a few other cosmetic changes, such as replacing the string "Your logo here". These don't affect the functionality of the application. You can download the project and compare the files.

Run the application and click the "Admin" link that appears at the top of the home page. The Admin page should look like the following:

Right now, the page doesn't do anything. In the next section, we'll use Knockout.js to create a dynamic UI.

Add Authorization

The Admin page is currently accessible to anyone visiting the site. Let's change this to restrict permission to administrators.

Start by adding an "Administrator" role and an administrator user. In Solution Explorer, expand the Filters folder and open the file named InitializeSimpleMembershipAttribute.cs. Locate the `SimpleMembershipInitializer` constructor. After the call to **WebSecurity.InitializeDatabaseConnection**, add the following code:

```
const string adminRole = "Administrator";
const string adminName = "Administrator";

if (!Roles.RoleExists(adminRole))
{
    Roles.CreateRole(adminRole);
}
if (!WebSecurity.UserExists(adminName))
{
    WebSecurity.CreateUserAndAccount(adminName, "password");
    Roles.AddUserToRole(adminName, adminRole);
}
```

This is a quick-and-dirty way to add the "Administrator" role and create a user for the role.

In Solution Explorer, expand the Controllers folder and open the HomeController.cs file. Add the **Authorize** attribute to the `Admin` method.

```
[Authorize(Roles="Administrator")]
public ActionResult Admin()
{
    return View();
}
```

Open the AdminController.cs file and add the **Authorize** attribute to the entire `AdminController` class.

```
[Authorize(Roles="Administrator")]
public class AdminController : ApiController
{
    // ...
```

NOTE

MVC and Web API both define **Authorize** attributes, in different namespaces. MVC uses **System.Web.Mvc.AuthorizeAttribute**, while Web API uses **System.Web.Http.AuthorizeAttribute**.

Now only administrators can view the Admin page. Also, if you send an HTTP request to the Admin controller, the request must contain an authentication cookie. If not, the server sends an HTTP 401 (Unauthorized) response. You can see this in Fiddler by sending a GET request to `http://localhost:*port*/api/admin`.

Part 5: Creating a Dynamic UI with Knockout.js

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

Creating a Dynamic UI with Knockout.js

In this section, we'll use Knockout.js to add functionality to the Admin view.

Knockout.js is a Javascript library that makes it easy to bind HTML controls to data. Knockout.js uses the Model-View-ViewModel (MVVM) pattern.

- The *model* is the server-side representation of the data in the business domain (in our case, products and orders).
- The *view* is the presentation layer (HTML).
- The *view-model* is a Javascript object that holds the model data. The view-model is a code abstraction of the UI. It has no knowledge of the HTML representation. Instead, it represents abstract features of the view, such as "a list of items".

The view is data-bound to the view-model. Updates to the view-model are automatically reflected in the view. The view-model also gets events from the view, such as button clicks, and performs operations on the model, such as creating an order.

First we'll define the view-model. After that, we will bind the HTML markup to the view-model.

Add the following Razor section to Admin.cshtml:

```
@section Scripts {
  @Scripts.Render("~/bundles/jqueryval")
  <script type="text/javascript" src="@Url.Content("~/Scripts/knockout-2.1.0.js")"></script>
  <script type="text/javascript">
  // View-model will go here
  </script>
}
```

You can add this section anywhere in the file. When the view is rendered, the section appears at the bottom of the HTML page, right before the closing </body> tag.

All of the script for this page will go inside the script tag indicated by the comment:

```
<script type="text/javascript">
  // View-model will go here
  </script>
```

First, define a view-model class:

```
function ProductsViewModel() {
    var self = this;
    self.products = ko.observableArray();
}
```

ko.observableArray is a special kind of object in Knockout, called an *observable*. From the Knockout.js documentation: An observable is a "JavaScript object that can notify subscribers about changes." When the contents of an observable change, the view is automatically updated to match.

To populate the `products` array, make an AJAX request to the web API. Recall that we stored the base URI for the API in the view bag (see Part 4 of the tutorial).

```
function ProductsViewModel() {
    var self = this;
    self.products = ko.observableArray();

    // New code
    var baseUri = '@ViewBag.ApiUrl';
    $.getJSON(baseUri, self.products);
}
```

Next, add functions to the view-model to create, update, and delete products. These functions submit AJAX calls to the web API and use the results to update the view-model.

```
function ProductsViewModel() {
    var self = this;
    self.products = ko.observableArray();

    var baseUri = '@ViewBag.ApiUrl';

    // New code
    self.create = function (formElement) {
        // If the form data is valid, post the serialized form data to the web API.
        $(formElement).validate();
        if ($(formElement).valid()) {
            $.post(baseUri, $(formElement).serialize(), null, "json")
                .done(function (o) {
                    // Add the new product to the view-model.
                    self.products.push(o);
                });
        }
    }

    self.update = function (product) {
        $.ajax({ type: "PUT", url: baseUri + '/' + product.Id, data: product });
    }

    self.remove = function (product) {
        // First remove from the server, then from the view-model.
        $.ajax({ type: "DELETE", url: baseUri + '/' + product.Id })
            .done(function () { self.products.remove(product); });
    }

    $.getJSON(baseUri, self.products);
}
```

Now the most important part: When the DOM is fulled loaded, call the **ko.applyBindings** function and pass in a new instance of the `ProductsViewModel`:

```
$(document).ready(function () {
    ko.applyBindings(new ProductsViewModel());
})
```

The **ko.applyBindings** method activates Knockout and wires up the view-model to the view.

Now that we have a view-model, we can create the bindings. In Knockout.js, you do this by adding `data-bind` attributes to HTML elements. For example, to bind an HTML list to an array, use the `foreach` binding:

```
<ul id="update-products" data-bind="foreach: products">
```

The `foreach` binding iterates through the array and creates child elements for each object in the array. Bindings on the child elements can refer to properties on the array objects.

Add the following bindings to the "update-products" list:

```
<ul id="update-products" data-bind="foreach: products">
    <li>
        <div>
            <div class="item">Product ID</div> <span data-bind="text: $data.Id"></span>
        </div>
        <div>
            <div class="item">Name</div>
            <input type="text" data-bind="value: $data.Name"/>
        </div>
        <div>
            <div class="item">Price ($)</div>
            <input type="text" data-bind="value: $data.Price"/>
        </div>
        <div>
            <div class="item">Actual Cost ($)</div>
            <input type="text" data-bind="value: $data.ActualCost"/>
        </div>
        <div>
            <input type="button" value="Update" data-bind="click: $root.update"/>
            <input type="button" value="Delete Item" data-bind="click: $root.remove"/>
        </div>
    </li>
</ul>
```

The `<li>` element occurs within the scope of the **foreach** binding. That means Knockout will render the element once for each product in the `products` array. All of the bindings within the `<li>` element refer to that product instance. For example, `$data.Name` refers to the `Name` property on the product.

To set the values of the text inputs, use the `value` binding. The buttons are bound to functions on the model-view, using the `click` binding. The product instance is passed as a parameter to each function. For more information, the Knockout.js documentation has good descriptions of the various bindings.

Next, add a binding for the **submit** event on the Add Product form:

```
<form id="addProduct" data-bind="submit: create">
```

This binding calls the `create` function on the view-model to create a new product.

Here is the complete code for the Admin view:

```
@model ProductStore.Models.Product
```

```
@{
    ViewBag.Title = "Admin";
}

@section Scripts {
  @Scripts.Render("~/bundles/jqueryval")
  <script type="text/javascript" src="@Url.Content("~/Scripts/knockout-2.0.0.js")"></script>
  <script type="text/javascript">
      function ProductsViewModel() {
          var self = this;
          self.products = ko.observableArray();

          var baseUri = '@ViewBag.ApiUrl';

          self.create = function (formElement) {
              // If valid, post the serialized form data to the web api
              $(formElement).validate();
              if ($(formElement).valid()) {
                  $.post(baseUri, $(formElement).serialize(), null, "json")
                      .done(function (o) { self.products.push(o); });
              }
          }

          self.update = function (product) {
              $.ajax({ type: "PUT", url: baseUri + '/' + product.Id, data: product });
          }

          self.remove = function (product) {
              // First remove from the server, then from the UI
              $.ajax({ type: "DELETE", url: baseUri + '/' + product.Id })
                  .done(function () { self.products.remove(product); });
          }

          $.getJSON(baseUri, self.products);
      }

      $(document).ready(function () {
          ko.applyBindings(new ProductsViewModel());
      })
  </script>
}

<h2>Admin</h2>
<div class="content">
    <div class="float-left">
    <ul id="update-products" data-bind="foreach: products">
        <li>
            <div>
                <div class="item">Product ID</div> <span data-bind="text: $data.Id"></span>
            </div>
            <div>
                <div class="item">Name</div>
                <input type="text" data-bind="value: $data.Name"/>
            </div>
            <div>
                <div class="item">Price ($)</div>
                <input type="text" data-bind="value: $data.Price"/>
            </div>
            <div>
                <div class="item">Actual Cost ($)</div>
                <input type="text" data-bind="value: $data.ActualCost"/>
            </div>
            <div>
                <input type="button" value="Update" data-bind="click: $root.update"/>
                <input type="button" value="Delete Item" data-bind="click: $root.remove"/>
            </div>
        </li>
    </ul>
    </div>
```

```
    <div class="float-right">
    <h2>Add New Product</h2>
    <form id="addProduct" data-bind="submit: create">
        @Html.ValidationSummary(true)
        <fieldset>
            <legend>Contact</legend>
            @Html.EditorForModel()
            <p>
                <input type="submit" value="Save" />
            </p>
        </fieldset>
    </form>
    </div>
</div>
```

Run the application, log in with the Administrator account, and click the "Admin" link. You should see the list of products, and be able to create, update, or delete products.

Part 6: Creating Product and Order Controllers

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

Add a Products Controller

The Admin controller is for users who have administrator privileges. Customers, on the other hand, can view products but cannot create, update, or delete them.

We can easily restrict access to the Post, Put, and Delete methods, while leaving the Get methods open. But look at the data that is returned for a product:

```
{"Id":1,"Name":"Tomato Soup","Price":1.39,"ActualCost":0.99}
```

The `ActualCost` property should not be visible to customers! The solution is to define a *data transfer object* (DTO) that includes a subset of properties that should be visible to customers. We will use LINQ to project `Product` instances to `ProductDTO` instances.

Add a class named `ProductDTO` to the Models folder.

```
namespace ProductStore.Models
{
    public class ProductDTO
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public decimal Price { get; set; }
    }
}
```

Now add the controller. In Solution Explorer, right-click the Controllers folder. Select **Add**, then select **Controller**. In the **Add Controller** dialog, name the controller "ProductsController". Under **Template**, select **Empty API controller**.

Replace everything in the source file with the following code:

```
namespace ProductStore.Controllers
{
    using System.Collections.Generic;
    using System.Linq;
    using System.Net;
    using System.Net.Http;
    using System.Web.Http;
    using ProductStore.Models;

    public class ProductsController : ApiController
    {
        private OrdersContext db = new OrdersContext();

        // Project products to product DTOs.
        private IQueryable<ProductDTO> MapProducts()
        {
            return from p in db.Products select new ProductDTO()
                { Id = p.Id, Name = p.Name, Price = p.Price };
        }

        public IEnumerable<ProductDTO> GetProducts()
        {
            return MapProducts().AsEnumerable();
        }

        public ProductDTO GetProduct(int id)
        {
            var product = (from p in MapProducts()
                           where p.Id == 1
                           select p).FirstOrDefault();
            if (product == null)
            {
                throw new HttpResponseException(
                    Request.CreateResponse(HttpStatusCode.NotFound));
            }
            return product;
        }

        protected override void Dispose(bool disposing)
        {
            db.Dispose();
            base.Dispose(disposing);
        }
    }
}
```

The controller still uses the `OrdersContext` to query the database. But instead of returning `Product` instances directly, we call `MapProducts` to project them onto `ProductDTO` instances:

```
return from p in db.Products select new ProductDTO()
    { Id = p.Id, Name = p.Name, Price = p.Price };
```

The `MapProducts` method returns an **IQueryable**, so we can compose the result with other query parameters. You can see this in the `GetProduct` method, which adds a **where** clause to the query:

```
var product = (from p in MapProducts()
    where p.Id == 1
    select p).FirstOrDefault();
```

Add an Orders Controller

Next, add a controller that lets users create and view orders.

We'll start with another DTO. In Solution Explorer, right-click the Models folder and add a class named `OrderDTO`. Use the following implementation:

```
namespace ProductStore.Models
{
    using System.Collections.Generic;

    public class OrderDTO
    {
        public class Detail
        {
            public int ProductID { get; set; }
            public string Product { get; set; }
            public decimal Price { get; set; }
            public int Quantity { get; set; }
        }
        public IEnumerable<Detail> Details { get; set; }
    }
}
```

Now add the controller. In Solution Explorer, right-click the Controllers folder. Select **Add**, then select **Controller**. In the **Add Controller** dialog, set the following options:

- Under **Controller Name**, enter "OrdersController".
- Under **Template**, select "API controller with read/write actions, using Entity Framework".
- Under **Model class**, select "Order (ProductStore.Models)".
- Under **Data context class**, select "OrdersContext (ProductStore.Models)".

Click **Add**. This adds a file named OrdersController.cs. Next, we need to modify the default implementation of the controller.

First, delete the `PutOrder` and `DeleteOrder` methods. For this sample, customers cannot modify or delete existing orders. In a real application, you would need lots of back-end logic to handle these cases. (For example, was the order already shipped?)

Change the `GetOrders` method to return just the orders that belong to the user:

```
public IEnumerable<Order> GetOrders()
{
    return db.Orders.Where(o => o.Customer == User.Identity.Name);
}
```

Change the `GetOrder` method as follows:

```
public OrderDTO GetOrder(int id)
{
    Order order = db.Orders.Include("OrderDetails.Product")
        .First(o => o.Id == id && o.Customer == User.Identity.Name);
    if (order == null)
    {
        throw new HttpResponseException(Request.CreateResponse(HttpStatusCode.NotFound));
    }

    return new OrderDTO()
    {
        Details = from d in order.OrderDetails
                  select new OrderDTO.Detail()
                      {
                          ProductID = d.Product.Id,
                          Product = d.Product.Name,
                          Price = d.Product.Price,
                          Quantity = d.Quantity
                      }
    };
}
```

Here are the changes that we made to the method:

- The return value is an `OrderDTO` instance, instead of an `Order`.
- When we query the database for the order, we use the DbQuery.Include method to fetch the related `OrderDetail` and `Product` entities.
- We flatten the result by using a projection.

The HTTP response will contain an array of products with quantities:

```
{"Details":[{"ProductID":1,"Product":"Tomato Soup","Price":1.39,"Quantity":2},
{"ProductID":3,"Product":"Yo yo","Price":6.99,"Quantity":1}]}
```

This format is easier for clients to consume than the original object graph, which contains nested entities (order, details, and products).

The last method to consider it `PostOrder`. Right now, this method takes an `Order` instance. But consider what happens if a client sends a request body like this:

```
{"Customer":"Alice","OrderDetails":[{"Quantity":1,"Product":{"Name":"Koala bears",
"Price":5,"ActualCost":1}}]}
```

This is a well-structured order, and Entity Framework will happily insert it into the database. But it contains a Product entity that did not exist previously. The client just created a new product in our database! This will be a surprise to the order fulfillment department, when they see an order for koala bears. The moral is, be really careful about the data you accept in a POST or PUT request.

To avoid this problem, change the `PostOrder` method to take an `OrderDTO` instance. Use the `OrderDTO` to create the `Order`.

```
var order = new Order()
{
    Customer = User.Identity.Name,
    OrderDetails = (from item in dto.Details select new OrderDetail()
        { ProductId = item.ProductID, Quantity = item.Quantity }).ToList()
};
```

Notice that we use the `ProductID` and `Quantity` properties, and we ignore any values that the client sent for either product name or price. If the product ID is not valid, it will violate the foreign key constraint in the database, and the insert will fail, as it should.

Here is the complete `PostOrder` method:

```
public HttpResponseMessage PostOrder(OrderDTO dto)
{
    if (ModelState.IsValid)
    {
        var order = new Order()
        {
            Customer = User.Identity.Name,
            OrderDetails = (from item in dto.Details select new OrderDetail()
                { ProductId = item.ProductID, Quantity = item.Quantity }).ToList()
        };

        db.Orders.Add(order);
        db.SaveChanges();

        HttpResponseMessage response = Request.CreateResponse(HttpStatusCode.Created, order);
        response.Headers.Location = new Uri(Url.Link("DefaultApi", new { id = order.Id }));
        return response;
    }
    else
    {
        return Request.CreateResponse(HttpStatusCode.BadRequest);
    }
}
```

Finally, add the **Authorize** attribute to the controller:

```
[Authorize]
public class OrdersController : ApiController
{
    // ...
```

Now only registered users can create or view orders.

Part 7: Creating the Main Page

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

Creating the Main Page

In this section, you will create the main application page. This page will be more complex than the Admin page, so we'll approach it in several steps. Along the way, you'll see some more advanced Knockout.js techniques. Here is the basic layout of the page:

- "Products" holds an array of products.
- "Cart" holds an array of products with quantities. Clicking "Add to Cart" updates the cart.
- "Orders" holds an array of order IDs.
- "Details" holds an order detail, which is an array of items (products with quantities)

We'll start by defining some basic layout in HTML, with no data binding or script. Open the file Views/Home/Index.cshtml and replace all of the contents with the following:

```
<div class="content">
    <!-- List of products -->
    <div class="float-left">
    <h1>Products</h1>
    <ul id="products">
    </ul>
    </div>

    <!-- Cart -->
    <div id="cart" class="float-right">
    <h1>Your Cart</h1>
        <table class="details ui-widget-content">
    </table>
    <input type="button" value="Create Order"/>
    </div>
</div>

<div id="orders-area" class="content" >
    <!-- List of orders -->
    <div class="float-left">
    <h1>Your Orders</h1>
    <ul id="orders">
    </ul>
    </div>

   <!-- Order Details -->
    <div id="order-details" class="float-right">
    <h2>Order #<span></span></h2>
    <table class="details ui-widget-content">
    </table>
    <p>Total: <span></span></p>
    </div>
</div>
```

Next, add a Scripts section and create an empty view-model:

```
@section Scripts {
  <script type="text/javascript" src="@Url.Content("~/Scripts/knockout-2.1.0.js")"></script>
  <script type="text/javascript">

    function AppViewModel() {
        var self = this;
        self.loggedIn = @(Request.IsAuthenticated ? "true" : "false");
    }

    $(document).ready(function () {
        ko.applyBindings(new AppViewModel());
    });

  </script>
}
```

Based on the design sketched earlier, our view model needs observables for products, cart, orders, and details. Add the following variables to the `AppViewModel` object:

```
self.products = ko.observableArray();
self.cart = ko.observableArray();
self.orders = ko.observableArray();
self.details = ko.observable();
```

Users can add items from the products list into the cart, and remove items from the cart. To encapsulate these functions, we'll create another view-model class that represents a product. Add the following code to

`AppViewModel`:

```
function AppViewModel() {
    // ...

    // NEW CODE
    function ProductViewModel(root, product) {
        var self = this;
        self.ProductId = product.Id;
        self.Name = product.Name;
        self.Price = product.Price;
        self.Quantity = ko.observable(0);

        self.addItemToCart = function () {
            var qty = self.Quantity();
            if (qty == 0) {
                root.cart.push(self);
            }
            self.Quantity(qty + 1);
        };

        self.removeAllFromCart = function () {
            self.Quantity(0);
            root.cart.remove(self);
        };
    }
}
```

The `ProductViewModel` class contains two functions that are used to move the product to and from the cart: `addItemToCart` adds one unit of the product to the cart, and `removeAllFromCart` removes all quantities of the product.

Users can select an existing order and get the order details. We'll encapsulate this functionality into another view-model:

```
function AppViewModel() {
    // ...

    // NEW CODE
    function OrderDetailsViewModel(order) {
        var self = this;
        self.items = ko.observableArray();
        self.Id = order.Id;

        self.total = ko.computed(function () {
            var sum = 0;
            $.each(self.items(), function (index, item) {
                sum += item.Price * item.Quantity;
            });
            return '$' + sum.toFixed(2);
        });

        $.getJSON("/api/orders/" + order.Id, function (order) {
            $.each(order.Details, function (index, item) {
                self.items.push(item);
            })
        });
    };
}
```

The `OrderDetailsViewModel` is initialized with an order, and it fetches the order details by sending an AJAX request to the server.

Also, notice the `total` property on the `OrderDetailsViewModel`. This property is a special kind of observable called a computed observable. As the name implies, a computed observable lets you data bind to a computed value—in this case, the total cost of the order.

Next, add these functions to `AppViewModel`:

- `resetCart` removes all items from the cart.
- `getDetails` gets the details for an order (by pushing a new `OrderDetailsViewModel` onto the `details` list).
- `createOrder` creates a new order and empties the cart.

```
function AppViewModel() {
    // ...

    // NEW CODE
    self.resetCart = function() {
        var items = self.cart.removeAll();
        $.each(items, function (index, product) {
            product.Quantity(0);
        });
    }

    self.getDetails = function (order) {
        self.details(new OrderDetailsViewModel(order));
    }

    self.createOrder = function () {
        var jqxhr = $.ajax({
            type: 'POST',
            url: "api/orders",
            contentType: 'application/json; charset=utf-8',
            data: ko.toJSON({ Details: self.cart }),
            dataType: "json",
            success: function (newOrder) {
                self.resetCart();
                self.orders.push(newOrder);
            },
            error: function (jqXHR, textStatus, errorThrown) {
                self.errorMessage(errorThrown);
            }
        });
    };
};
```

Finally, initialize the view model by making AJAX requests for the products and orders:

```
function AppViewModel() {
    // ...

    // NEW CODE
    // Initialize the view-model.
    $.getJSON("/api/products", function (products) {
        $.each(products, function (index, product) {
            self.products.push(new ProductViewModel(self, product));
        })
    });

    $.getJSON("api/orders", self.orders);
};
```

OK, that's a lot of code, but we built it up step-by-step, so hopefully the design is clear. Now we can add some Knockout.js bindings to the HTML.

Products

Here are the bindings for the product list:

```
<ul id="products" data-bind="foreach: products">
    <li>
        <div>
            <span data-bind="text: Name"></span>
            <span class="price" data-bind="text: '$' + Price"></span>
        </div>
        <div data-bind="if: $parent.loggedIn">
            <button data-bind="click: addItemToCart">Add to Order</button>
        </div>
    </li>
</ul>
```

This iterates over the products array and displays the name and price. The "Add to Order" button is visible only when the user is logged in.

The "Add to Order" button calls `addItemToCart` on the `ProductViewModel` instance for the product. This demonstrates a nice feature of Knockout.js: When a view-model contains other view-models, you can apply the bindings to the inner model. In this example, the bindings within the `foreach` are applied to each of the `ProductViewModel` instances. This approach is much cleaner than putting all of the functionality into a single view-model.

Cart

Here are the bindings for the cart:

```
<div id="cart" class="float-right" data-bind="visible: cart().length > 0">
<h1>Your Cart</h1>
    <table class="details ui-widget-content">
    <thead>
        <tr><td>Item</td><td>Price</td><td>Quantity</td><td></td></tr>
    </thead>
    <tbody data-bind="foreach: cart">
        <tr>
            <td><span data-bind="text: $data.Name"></span></td>
            <td>$<span data-bind="text: $data.Price"></span></td>
            <td class="qty"><span data-bind="text: $data.Quantity()"></span></td>
            <td><a href="#" data-bind="click: removeAllFromCart">Remove</a></td>
        </tr>
    </tbody>
</table>
<input type="button" data-bind="click: createOrder" value="Create Order"/>
```

This iterates over the cart array and displays the name, price, and quantity. Note that the "Remove" link and the "Create Order" button are bound to view-model functions.

Orders

Here are the bindings for the orders list:

```
<h1>Your Orders</h1>
<ul id="orders" data-bind="foreach: orders">
<li class="ui-widget-content">
    <a href="#" data-bind="click: $root.getDetails">
        Order # <span data-bind="text: $data.Id"></span></a>
</li>
</ul>
```

This iterates over the orders and shows the order ID. The click event on the link is bound to the `getDetails` function.

Order Details

Here are the bindings for the order details:

```
<div id="order-details" class="float-right" data-bind="if: details()">
<h2>Order #<span data-bind="text: details().Id"></span></h2>
<table class="details ui-widget-content">
    <thead>
        <tr><td>Item</td><td>Price</td><td>Quantity</td><td>Subtotal</td></tr>
    </thead>
    <tbody data-bind="foreach: details().items">
        <tr>
            <td><span data-bind="text: $data.Product"></span></td>
            <td><span data-bind="text: $data.Price"></span></td>
            <td><span data-bind="text: $data.Quantity"></span></td>
            <td>
                <span data-bind="text: ($data.Price * $data.Quantity).toFixed(2)"></span>
            </td>
        </tr>
    </tbody>
</table>
<p>Total: <span data-bind="text: details().total"></span></p>
</div>
```

This iterates over the items in the order and displays the product, price, and quantity. The surrounding div is visible only if the details array contains one or more items.

Conclusion

In this tutorial, you created an application that uses Entity Framework to communicate with the database, and ASP.NET Web API to provide a public-facing interface on top of the data layer. We use ASP.NET MVC 4 to render the HTML pages, and Knockout.js plus jQuery to provide dynamic interactions without page reloads.

Self-Host ASP.NET Web API 1 (C#)

2/20/2020 • 6 minutes to read • Edit Online

by Mike Wasson

This tutorial shows how to host a web API inside a console application. ASP.NET Web API does not require IIS. You can self-host a web API in your own host process.

New applications should use OWIN to self-host Web API. See Use OWIN to Self-Host ASP.NET Web API 2.

Software versions used in the tutorial

- Web API 1
- Visual Studio 2012

Create the Console Application Project

Start Visual Studio and select **New Project** from the **Start** page. Or, from the **File** menu, select **New** and then **Project**.

In the **Templates** pane, select **Installed Templates** and expand the **Visual C#** node. Under **Visual C#**, select **Windows**. In the list of project templates, select **Console Application**. Name the project "SelfHost" and click **OK**.

Set the Target Framework (Visual Studio 2010)

If you are using Visual Studio 2010, change the target framework to .NET Framework 4.0. (By default, the project template targets the .Net Framework Client Profile.)

In Solution Explorer, right-click the project and select **Properties**. In the **Target framework** dropdown list, change the target framework to .NET Framework 4.0. When prompted to apply the change, click **Yes**.

Install NuGet Package Manager

The NuGet Package Manager is the easiest way to add the Web API assemblies to a non-ASP.NET project.

To check if NuGet Package Manager is installed, click the **Tools** menu in Visual Studio. If you see a menu item called **NuGet Package Manager**, then you have NuGet Package Manager.

To install NuGet Package Manager:

1. Start Visual Studio.
2. From the **Tools** menu, select **Extensions and Updates**.
3. In the **Extensions and Updates** dialog, select **Online**.
4. If you don't see "NuGet Package Manager", type "nuget package manager" in the search box.
5. Select the NuGet Package Manager and click **Download**.
6. After the download completes, you will be prompted to install.
7. After the installation completes, you might be prompted to restart Visual Studio.

Add the Web API NuGet Package

After NuGet Package Manager is installed, add the Web API Self-Host package to your project.

1. From the **Tools** menu, select **NuGet Package Manager**. *Note*: If do you not see this menu item, make sure that NuGet Package Manager installed correctly.

2. Select **Manage NuGet Packages for Solution**
3. In the **Manage NugGet Packages** dialog, select **Online**.
4. In the search box, type "Microsoft.AspNet.WebApi.SelfHost".
5. Select the ASP.NET Web API Self Host package and click **Install**.
6. After the package installs, click **Close** to close the dialog.

> **NOTE**
>
> Make sure to install the package named Microsoft.AspNet.WebApi.SelfHost, not AspNetWebApi.SelfHost.

Create the Model and Controller

This tutorial uses the same model and controller classes as the Getting Started tutorial.

Add a public class named `Product`.

```
namespace SelfHost
{
    public class Product
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public string Category { get; set; }
        public decimal Price { get; set; }
    }
}
```

Add a public class named `ProductsController`. Derive this class from **System.Web.Http.ApiController**.

```
namespace SelfHost
{
    using System;
    using System.Collections.Generic;
    using System.Linq;
    using System.Net;
    using System.Web.Http;

    public class ProductsController : ApiController
    {
        Product[] products = new Product[]
        {
            new Product { Id = 1, Name = "Tomato Soup", Category = "Groceries", Price = 1 },
            new Product { Id = 2, Name = "Yo-yo", Category = "Toys", Price = 3.75M },
            new Product { Id = 3, Name = "Hammer", Category = "Hardware", Price = 16.99M }
        };

        public IEnumerable<Product> GetAllProducts()
        {
            return products;
        }

        public Product GetProductById(int id)
        {
            var product = products.FirstOrDefault((p) => p.Id == id);
            if (product == null)
            {
                throw new HttpResponseException(HttpStatusCode.NotFound);
            }
            return product;
        }

        public IEnumerable<Product> GetProductsByCategory(string category)
        {
            return products.Where(p => string.Equals(p.Category, category,
                    StringComparison.OrdinalIgnoreCase));
        }
    }
}
```

For more information about the code in this controller, see the Getting Started tutorial. This controller defines three GET actions:

URI	DESCRIPTION
/api/products	Get a list of all products.
/api/products/*id*	Get a product by ID.
/api/products/?category=*category*	Get a list of products by category.

Host the Web API

Open the file Program.cs and add the following using statements:

```
using System.Web.Http;
using System.Web.Http.SelfHost;
```

Add the following code to the **Program** class.

```
var config = new HttpSelfHostConfiguration("http://localhost:8080");

config.Routes.MapHttpRoute(
    "API Default", "api/{controller}/{id}",
    new { id = RouteParameter.Optional });

using (HttpSelfHostServer server = new HttpSelfHostServer(config))
{
    server.OpenAsync().Wait();
    Console.WriteLine("Press Enter to quit.");
    Console.ReadLine();
}
```

(Optional) Add an HTTP URL Namespace Reservation

This application listens to `http://localhost:8080/`. By default, listening at a particular HTTP address requires administrator privileges. When you run the tutorial, therefore, you may get this error: "HTTP could not register URL http://+:8080/" There are two ways to avoid this error:

- Run Visual Studio with elevated administrator permissions, or
- Use Netsh.exe to give your account permissions to reserve the URL.

To use Netsh.exe, open a command prompt with administrator privileges and enter the following command:following command:

```
netsh http add urlacl url=http://+:8080/ user=machine\username
```

where *machine**username* is your user account.

When you are finished self-hosting, be sure to delete the reservation:

```
netsh http delete urlacl url=http://+:8080/
```

Call the Web API from a Client Application (C#)

Let's write a simple console application that calls the web API.

Add a new console application project to the solution:

- In Solution Explorer, right-click the solution and select **Add New Project**.
- Create a new console application named "ClientApp".

Use NuGet Package Manager to add the ASP.NET Web API Core Libraries package:

- From the Tools menu, select **NuGet Package Manager**.
- Select **Manage NuGet Packages for Solution**
- In the **Manage NuGet Packages** dialog, select **Online**.
- In the search box, type "Microsoft.AspNet.WebApi.Client".
- Select the Microsoft ASP.NET Web API Client Libraries package and click **Install**.

Add a reference in ClientApp to the SelfHost project:

- In Solution Explorer, right-click the ClientApp project.
- Select **Add Reference**.
- In the **Reference Manager** dialog, under **Solution**, select **Projects**.
- Select the SelfHost project.
- Click **OK**.

Open the Client/Program.cs file. Add the following **using** statement:

```
using System.Net.Http;
```

Add a static **HttpClient** instance:

```
namespace Client
{
    class Program
    {
        static HttpClient client = new HttpClient();
    }
}
```

Add the following methods to list all products, list a product by ID, and list products by category.

```
static void ListAllProducts()
{
    HttpResponseMessage resp = client.GetAsync("api/products").Result;
    resp.EnsureSuccessStatusCode();

    var products = resp.Content.ReadAsAsync<IEnumerable<SelfHost.Product>>().Result;
    foreach (var p in products)
    {
        Console.WriteLine("{0} {1} {2} ({3})", p.Id, p.Name, p.Price, p.Category);
    }
}

static void ListProduct(int id)
{
    var resp = client.GetAsync(string.Format("api/products/{0}", id)).Result;
    resp.EnsureSuccessStatusCode();

    var product = resp.Content.ReadAsAsync<SelfHost.Product>().Result;
    Console.WriteLine("ID {0}: {1}", id, product.Name);
}

static void ListProducts(string category)
{
    Console.WriteLine("Products in '{0}':", category);

    string query = string.Format("api/products?category={0}", category);

    var resp = client.GetAsync(query).Result;
    resp.EnsureSuccessStatusCode();

    var products = resp.Content.ReadAsAsync<IEnumerable<SelfHost.Product>>().Result;
    foreach (var product in products)
    {
        Console.WriteLine(product.Name);
    }
}
```

Each of these methods follows the same pattern:

1. Call **HttpClient.GetAsync** to send a GET request to the appropriate URI.
2. Call **HttpResponseMessage.EnsureSuccessStatusCode**. This method throws an exception if the HTTP response status is an error code.
3. Call **ReadAsAsync<T>** to deserialize a CLR type from the HTTP response. This method is an extension method, defined in **System.Net.Http.HttpContentExtensions**.

The **GetAsync** and **ReadAsAsync** methods are both asynchronous. They return **Task** objects that represent the asynchronous operation. Getting the **Result** property blocks the thread until the operation completes.

For more information about using HttpClient, including how to make non-blocking calls, see Calling a Web API From a .NET Client.

Before calling these methods, set the BaseAddress property on the HttpClient instance to "`http://localhost:8080`". For example:

```
static void Main(string[] args)
{
    client.BaseAddress = new Uri("http://localhost:8080");

    ListAllProducts();
    ListProduct(1);
    ListProducts("toys");

    Console.WriteLine("Press Enter to quit.");
    Console.ReadLine();
}
```

This should output the following. (Remember to run the SelfHost application first.)

```
1 Tomato Soup 1.0 (Groceries)
2 Yo-yo 3.75 (Toys)
3 Hammer 16.99 (Hardware)
ID 1: Tomato Soup
Products in 'toys':
Yo-yo
Press Enter to quit.
```

Build RESTful APIs with ASP.NET Web API

2/20/2020 • 24 minutes to read • Edit Online

by Web Camps Team

> Hands on lab: Use Web API in ASP.NET 4.x to build a simple REST API for a contact manager application. You will also build a client to consume the API.

In recent years, it has become clear that HTTP is not just for serving up HTML pages. It is also a powerful platform for building Web APIs, using a handful of verbs (GET, POST, and so forth) plus a few simple concepts such as *URIs* and *headers*. ASP.NET Web API is a set of components that simplify HTTP programming. Because it is built on top of the ASP.NET MVC runtime, Web API automatically handles the low-level transport details of HTTP. At the same time, Web API naturally exposes the HTTP programming model. In fact, one goal of Web API is to *not* abstract away the reality of HTTP. As a result, Web API is both flexible and easy to extend. The REST architectural style has proven to be an effective way to leverage HTTP - although it is certainly not the only valid approach to HTTP. The contact manager will expose the RESTful for listing, adding and removing contacts, among others.

This lab requires a basic understanding of HTTP, REST, and assumes you have a basic working knowledge of HTML, JavaScript, and jQuery.

> **NOTE**
>
> The ASP.NET Web site has an area dedicated to the ASP.NET Web API framework at https://asp.net/web-api. This site will continue to provide late-breaking information, samples, and news related to Web API, so check it frequently if you'd like to delve deeper into the art of creating custom Web APIs available to virtually any device or development framework.
>
> ASP.NET Web API, similar to ASP.NET MVC 4, has great flexibility in terms of separating the service layer from the controllers allowing you to use several of the available Dependency Injection frameworks fairly easy. There is a good sample in MSDN that shows how to use Ninject for dependency injection in an ASP.NET Web API project that you can download it from here.

All sample code and snippets are included in the Web Camps Training Kit, available at https://go.microsoft.com/fwlink/?LinkID=248297&clcid=0x409.

Objectives

In this hands-on lab, you will learn how to:

- Implement a RESTful Web API
- Call the API from an HTML client

Prerequisites

The following is required to complete this hands-on lab:

- Microsoft Visual Studio Express 2012 for Web or superior (read Appendix B for instructions on how to install it).

Setup

Installing Code Snippets

For convenience, much of the code you will be managing along this lab is available as Visual Studio code snippets. To install the code snippets run `.\Source\Setup\CodeSnippets.vsi` file.

If you are not familiar with the Visual Studio Code Snippets, and want to learn how to use them, you can refer to the appendix from this document "Appendix A: Using Code Snippets".

Exercises

This hands-on lab includes the following exercise:

1. Exercise 1: Create a Read-Only Web API
2. Exercise 2: Create a Read/Write Web API
3. Exercise 3: Consume the Web API from an HTML Client

> **NOTE**
>
> Each exercise is accompanied by an **End** folder containing the resulting solution you should obtain after completing the exercises. You can use this solution as a guide if you need additional help working through the exercises.

Estimated time to complete this lab: **60 minutes**.

Exercise 1: Create a Read-Only Web API

In this exercise, you will implement the read-only GET methods for the contact manager.

Task 1 - Creating the API Project

In this task, you will use the new ASP.NET web project templates to create a Web API web application.

1. Run **Visual Studio 2012 Express for Web**, to do this go to **Start** and type **VS Express for Web** then press **Enter**.

2. From the **File** menu, select **New Project**. Select the **Visual C# | Web** project type from the project type tree view, then select the **ASP.NET MVC 4 Web Application** project type. Set the project's **Name** to *ContactManager* and the **Solution name** to *Begin*, then click **OK**.

Creating a new ASP.NET MVC 4.0 Web Application Project

3. In the ASP.NET MVC 4 project type dialog, select the **Web API** project type. Click **OK**.

Specifying the Web API project type

Task 2 - Creating the Contact Manager API Controllers

In this task, you will create the controller classes in which API methods will reside.

1. Delete the file named **ValuesController.cs** within **Controllers** folder from the project.

2. Right-click the **Controllers** folder in the project and select **Add | Controller** from the context menu.

Adding a new controller to the project

3. In the **Add Controller** dialog that appears, select **Empty API Controller** from the Template menu. Name the controller class **ContactController**. Then, click **Add.**

Using the Add Controller dialog to create a new Web API controller

4. Add the following code to the **ContactController**.

(Code Snippet - *Web API Lab - Ex01 - Get API Method*)

```
public string[] Get()
{
    return new string[]
    {
        "Hello",
        "World"
    };
}
```

5. Press **F5** to debug the application. The default home page for a Web API project should appear.

The default home page of an ASP.NET Web API application

6. In the Internet Explorer window, press the **F12** key to open the **Developer Tools** window. Click the **Network** tab, and then click the **Start Capturing** button to begin capturing network traffic into the window.

Opening the network tab and initiating network capture

7. Append the URL in the browser's address bar with **/api/contact** and press enter. The transmission details will appear in the network capture window. Note that the response's MIME type is **application/json**. This demonstrates how the default output format is JSON.

Viewing the output of the Web API request in the Network view

> **NOTE**
>
> Internet Explorer 10's default behavior at this point will be to ask if the user would like to save or open the stream resulting from the Web API call. The output will be a text file containing the JSON result of the Web API URL call. Do not cancel the dialog in order to be able to watch the response's content through Developers Tool window.

8. Click the **Go to detailed view** button to see more details about the response of this API call.

Switch to Detailed View

9. Click the **Response body** tab to view the actual JSON response text.

Viewing the JSON output text in the network monitor

Task 3 - Creating the Contact Models and Augment the Contact Controller

In this task, you will create the controller classes in which API methods will reside.

1. Right-click the **Models** folder and select **Add | Class...** from the context menu.

Adding a new model to the web application

2. In the **Add New Item** dialog, name the new file **Contact.cs** and click **Add.**

Creating the new Contact class file

3. Add the following highlighted code to the **Contact** class.

(Code Snippet - *Web API Lab - Ex01 - Contact Class*)

```
public class Contact
{
    public int Id { get; set; }

    public string Name { get; set; }
}
```

4. In the **ContactController** class, select the word **string** in method definition of the **Get** method, and type the word *Contact*. Once the word is typed in, an indicator will appear at the beginning of the word **Contact**. Either hold down the **Ctrl** key and press the period (.) key or click the icon using your mouse to open up the assistance dialog in the code editor, to automatically fill in the **using** directive for the Models namespace.

Using Intellisense assistance for namespace declarations

5. Modify the code for the **Get** method so that it returns an array of Contact model instances.

(Code Snippet - *Web API Lab - Ex01 - Returning a list of contacts*)

```
public Contact[] Get()
{
    return new Contact[]
    {
        new Contact
        {
            Id = 1,
            Name = "Glenn Block"
        },
        new Contact
        {
            Id = 2,
            Name = "Dan Roth"
        }
    };
}
```

6. Press **F5** to debug the web application in the browser. To view the changes made to the response output of the API, perform the following steps.

   a. Once the browser opens, press **F12** if the developer tools are not open yet.

   b. Click the **Network** tab.

c. Press the **Start Capturing** button.

d. Add the URL suffix **/api/contact** to the URL in the address bar and press the **Enter** key.

e. Press the **Go to detailed view** button.

f. Select the **Response body** tab. You should see a JSON string representing the serialized form of an array of Contact instances.

JSON serialized output of a complex Web API method call

Task 4 - Extracting Functionality into a Service Layer

This task will demonstrate how to extract functionality into a Service layer to make it easy for developers to separate their service functionality from the controller layer, thereby allowing reusability of the services that actually do the work.

1. Create a new folder in the solution root and name it **Services**. To do this, right-click **ContactManager** project, select **Add | New Folder**, name it *Services*.

Creating Services folder

2. Right-click the **Services** folder and select **Add | Class...** from the context menu.

Adding a new class to the Services folder

3. When the **Add New Item** dialog appears, name the new class **ContactRepository** and click **Add**.

Creating a class file to contain the code for the Contact Repository service layer

4. Add a using directive to the **ContactRepository.cs** file to include the models namespace.

```
using ContactManager.Models;
```

5. Add the following highlighted code to the **ContactRepository.cs** file to implement GetAllContacts method.

   (Code Snippet - *Web API Lab - Ex01 - Contact Repository*)

```
public class ContactRepository
{
    public Contact[] GetAllContacts()
    {
        return new Contact[]
        {
            new Contact
            {
                Id = 1,
                Name = "Glenn Block"
            },
            new Contact
            {
                Id = 2,
                Name = "Dan Roth"
            }
        };
    }
}
```

6. Open the **ContactController.cs** file if it is not already open.

7. Add the following using statement to the namespace declaration section of the file.

```
using ContactManager.Services;
```

8. Add the following highlighted code to the **ContactController.cs** class to add a private field to represent the instance of the repository, so that the rest of the class members can make use of the service implementation.

   (Code Snippet - *Web API Lab - Ex01 - Contact Controller*)

```
public class ContactController : ApiController
{
    private ContactRepository contactRepository;

    public ContactController()
    {
        this.contactRepository = new ContactRepository();
    }
    ...
}
```

9. Change the **Get** method so that it makes use of the contact repository service.

   (Code Snippet - *Web API Lab - Ex01 - Returning a list of contacts via the repository*)

```
public Contact[] Get()
{
    return contactRepository.GetAllContacts();
}
```

10. Put a breakpoint on the **ContactController**'s **Get** method definition.

```
namespace ContactManager.Controllers
{
    public class ContactController : ApiController
    {
        private ContactRepository contactRepository;

        public ContactController()
        {
            this.contactRepository = new ContactRepository();
        }

        public Contact[] Get()
        {
            return this.contactRepository.GetAllContacts();
        }
    }
}
```

Adding breakpoints to the contact controller 11. Press **F5** to run the application. 12. When the browser opens, press **F12** to open the developer tools. 13. Click the **Network** tab. 14. Click the **Start Capturing** button. 15. Append the URL in the address bar with the suffix **/api/contact** and press **Enter** to load the API controller. 16. Visual Studio 2012 should break once **Get** method begins execution.

```
public Contact[] Get()
{
    return this.contactRepository.GetAllContacts();
}
```

this.contactRepository {ContactManager.Services.ContactRepository}

Breaking within the Get method 17. Press **F5** to continue. 18. Go back to Internet Explorer if it is not already in focus. Note the network capture window.

```
![Network view in Internet Explorer showing results of the Web API call](build-restful-apis-with-aspnet-web-
api/_static/image19.png "Network view in Internet Explorer showing results of the Web API call")

*Network view in Internet Explorer showing results of the Web API call*
```

19. Click the **Go to detailed view** button.

20. Click the **Response body** tab. Note the JSON output of the API call, and how it represents the two contacts retrieved by the service layer.

HTML CSS Console Script Profiler Network Search Captured Traffic...

Stop capturing | Back to summary view | < Prev | 1 / 1 | Next > | Clear

URL: http://localhost:53384/api/contact

Request headers | Request body | Response headers | Response body | Cookies | Initiator | Timings

```
1 [{"Id":1,"Name":"Glenn Block"},{"Id":2,"Name":"Dan Roth"}]
```

Do you want to open or save **contact.json** (58 bytes) from **localhost**? Open | Save | Cancel

Viewing the JSON output from the Web API in the developer tools window

Exercise 2: Create a Read/Write Web API

In this exercise, you will implement POST and PUT methods for the contact manager to enable it with data-editing features.

Task 1 - Opening the Web API Project

In this task, you will prepare to enhance the Web API project created in Exercise 1 so that it can accept user input.

1. Run **Visual Studio 2012 Express for Web**, to do this go to **Start** and type **VS Express for Web** then press **Enter**.
2. Open the **Begin** solution located at **Source/Ex02-ReadWriteWebAPI/Begin/** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.
   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.
   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.
   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

3. Open the **Services/ContactRepository.cs** file.

Task 2 - Adding Data-Persistence Features to the Contact Repository Implementation

In this task, you will augment the ContactRepository class of the Web API project created in Exercise 1 so that it can persist and accept user input and new Contact instances.

1. Add the following constant to the **ContactRepository** class to represent the name of the web server cache item key name later in this exercise.

```
private const string CacheKey = "ContactStore";
```

2. Add a constructor to the **ContactRepository** containing the following code.

   (Code Snippet - *Web API Lab - Ex02 - Contact Repository Constructor*)

```
public ContactRepository()
{
    var ctx = HttpContext.Current;

    if (ctx != null)
    {
        if (ctx.Cache[CacheKey] == null)
        {
            var contacts = new Contact[]
            {
                new Contact
                {
                    Id = 1, Name = "Glenn Block"
                },
                new Contact
                {
                    Id = 2, Name = "Dan Roth"
                }
            };

            ctx.Cache[CacheKey] = contacts;
        }
    }
}
```

3. Modify the code for the **GetAllContacts** method as demonstrated below.

   (Code Snippet - *Web API Lab - Ex02 - Get All Contacts*)

```
public Contact[] GetAllContacts()
{
    var ctx = HttpContext.Current;

    if (ctx != null)
    {
        return (Contact[])ctx.Cache[CacheKey];
    }

    return new Contact[]
        {
            new Contact
            {
                Id = 0,
                Name = "Placeholder"
            }
        };
}
```

> **NOTE**
>
> This example is for demonstration purposes and will use the web server's cache as a storage medium, so that the values will be available to multiple clients simultaneously, rather than use a Session storage mechanism or a Request storage lifetime. One could use Entity Framework, XML storage, or any other variety in place of the web server cache.

4. Implement a new method named **SaveContact** to the **ContactRepository** class to do the work of saving a contact. The **SaveContact** method should take a single **Contact** parameter and return a Boolean value indicating success or failure.

   (Code Snippet - *Web API Lab - Ex02 - Implementing the SaveContact Method*)

```
public bool SaveContact(Contact contact)
{
    var ctx = HttpContext.Current;

    if (ctx != null)
    {
         try
         {
              var currentData = ((Contact[])ctx.Cache[CacheKey]).ToList();
              currentData.Add(contact);
              ctx.Cache[CacheKey] = currentData.ToArray();

              return true;
         }
         catch (Exception ex)
         {
              Console.WriteLine(ex.ToString());
              return false;
         }
    }

    return false;
}
```

Exercise 3: Consume the Web API from an HTML Client

In this exercise, you will create an HTML client to call the Web API. This client will facilitate data exchange with the Web API using JavaScript and will display the results in a web browser using HTML markup.

Task 1 - Modifying the Index View to Provide a GUI for Displaying Contacts

In this task, you will modify the default Index view of the web application to support the requirement of displaying the list of existing contacts in an HTML browser.

1. Open **Visual Studio 2012 Express for Web** if it is not already open.
2. Open the **Begin** solution located at **Source/Ex03-ConsumingWebAPI/Begin/** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.
   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.
   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.
   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

3. Open the **Index.cshtml** file located at **Views/Home** folder.
4. Replace the HTML code within the div element with id **body** so that it looks like the following code.

```
<div id="body">
    <ul id="contacts"></ul>
</div>
```

5. Add the following Javascript code at the bottom of the file to perform the HTTP request to the Web API.

```
@section scripts{
<script type="text/javascript">
$(function()
{
        $.getJSON('/api/contact', function(contactsJsonPayload)
        {
            $(contactsJsonPayload).each(function(i, item)
            {
                $('#contacts').append('<li>' + item.Name + '</li>');
            });
        });
});
</script>
}
```

6. Open the **ContactController.cs** file if it is not already open.

7. Place a breakpoint on the **Get** method of the **ContactController** class.

```
public Contact[] Get()
{
    return this.contactRepository.GetAllContacts();
}
```

Placing a breakpoint on the Get method of the API controller

8. Press **F5** to run the project. The browser will load the HTML document.

> **NOTE**
>
> Ensure that you are browsing to the root URL of your application.

9. Once the page loads and the JavaScript executes, the breakpoint will be hit and the code execution will pause in the controller.

```
public Contact[] Get()
{
    return this.contactRepository.GetAllContacts();
}
```

Debugging into the Web API call using Visual Studio 2012 Express for Web

10. Remove the breakpoint and press **F5** or the debugging toolbar's **Continue** button to continue loading the view in the browser. Once the Web API call completes you should see the contacts returned from the Web API call displayed as list items in the browser.

Results of the API call displayed in the browser as list items

11. Stop debugging.

Task 2 - Modifying the Index View to Provide a GUI for Creating Contacts

In this task, you will continue to modify the Index view of the MVC application. A form will be added to the HTML page that will capture user input and send it to the Web API to create a new Contact, and a new Web API controller method will be created to collect date from the GUI.

1. Open the **ContactController.cs** file.

2. Add a new method to the controller class named **Post** as shown in the following code.

   (Code Snippet - *Web API Lab - Ex03 - Post Method*)

```
public HttpResponseMessage Post(Contact contact)
{
    this.contactRepository.SaveContact(contact);

    var response = Request.CreateResponse<Contact>(System.Net.HttpStatusCode.Created, contact);

    return response;
}
```

3. Open the **Index.cshtml** file in Visual Studio if it is not already open.

4. Add the HTML code below to the file just after the unordered list you added in the previous task.

```
<form id="saveContactForm" method="post">
<h3>Create a new Contact</h3>
<p>
    <label for="contactId">Contact Id:</label>
    <input type="text" name="Id" />
</p>
<p>
    <label for="contactName">Contact Name:</label>
    <input type="text" name="Name" />
</p>
<input type="button" id="saveContact" value="Save" />
</form>
```

5. Within the script element at the bottom of the document, add the following highlighted code to handle button-click events, which will post the data to the Web API using an HTTP POST call.

```
<script type="text/javascript">
...
$('#saveContact').click(function()
        {
             $.post("api/contact",
                   $("#saveContactForm").serialize(),
                   function(value)
                   {
                        $('#contacts').append('<li>' + value.Name + '</li>');
                   },
                   "json"
             );
        });
</script>
```

6. In **ContactController.cs**, place a breakpoint on the **Post** method.

7. Press **F5** to run the application in the browser.

8. Once the page is loaded in the browser, type in a new contact name and Id and click the **Save** button.

The client HTML document loaded in the browser

9. When the debugger window breaks in the **Post** method, take a look at the properties of the **contact** parameter. The values should match the data you entered in the form.

```
public HttpResponseMessage Post(Contact contact)
{
    this.contactRepository.SaveContact(contact);

    var response = Request.CreateResponse<Contact>(System.Net.HttpStatusCode.Created, contact);

    return response;
}
}
}
```

100 %

Locals

Name	Value
this	{ContactManager.Controllers.ContactController}
contact	{ContactManager.Models.Contact}
Id	42
Name	"John Doe"
response	null

The Contact object being sent to the Web API from the client

10. Step through the method in the debugger until the **response** variable has been created. Upon inspection in the **Locals** window in the debugger, you'll see that all the properties have been set.

```
public HttpResponseMessage Post(Contact contact)
{
    this.contactRepository.SaveContact(contact);

    var response = Request.CreateResponse<Contact>(System.Net.HttpStatusCode.Created, contact);

    return response;
}
}
}
```

100 %

Locals

Name	Value
contact	{ContactManager.Models.Contact}
Id	42
Name	"John Doe"
response	{StatusCode: 201, ReasonPhrase: 'Created', Version: 1.1, Content: System.Net.Http.ObjectContent`1[[ContactManager.Models.Contact, Co
Content	{System.Net.Http.ObjectContent<ContactManager.Models.Contact>}
Headers	{}
IsSuccessStatusCode	true
ReasonPhrase	"Created"
RequestMessage	{Method: POST, RequestUri: 'http://localhost:53384/api/contact', Version: 1.1, Content: System.Net.Http.StreamContent, Headers:{ Cache
StatusCode	Created
Version	{1.1}

The response following creation in the debugger 11. If you press **F5** or click **Continue** in the debugger the request will complete. Once you switch back to the browser, the new contact has been added to the list of contacts stored by the **ContactRepository** implementation.

The browser reflects successful creation of the new contact instance

> **NOTE**
>
> Additionally, you can deploy this application to Azure following Appendix C: Publishing an ASP.NET MVC 4 Application using Web Deploy.

Summary

This lab has introduced you to the new ASP.NET Web API framework and to the implementation of RESTful Web APIs using the framework. From here, you could create a new repository that facilitates data persistence using any number of mechanisms and wire that service up rather than the simple one provided as an example in this lab. Web API supports a number of additional features, such as enabling communication from non-HTML clients written in any language that supports HTTP and JSON or XML. The ability to host a Web API outside of a typical web application is also possible, as well as is the ability to create your own serialization formats.

The ASP.NET Web site has an area dedicated to the ASP.NET Web API framework at [https://asp.net/web-api] (https://asp.net/web-api). This site will continue to provide late-breaking information, samples, and news related to Web API, so check it frequently if you'd like to delve deeper into the art of creating custom Web APIs available to virtually any device or development framework.

Appendix A: Using Code Snippets

With code snippets, you have all the code you need at your fingertips. The lab document will tell you exactly when you can use them, as shown in the following figure.

6. Insert the following code inside the body of the **Run** method.

(Code Snippet – *AzurePlatformTrainingKit - Ex1-Task 1 -Step 5- Run method*)

C#

```
public override void Run()
{
  while (true)
  {
    // retrieve a new message from the queue
    CloudQueueMessage message = queue.GetMessage();
    if (message != null)
    {
      ProcessMessage(message);
      queue.DeleteMessage(msg);
    }
  }
}
```

Using Visual Studio code snippets to insert code into your project

To add a code snippet using the keyboard (C# only)

1. Place the cursor where you would like to insert the code.
2. Start typing the snippet name (without spaces or hyphens).
3. Watch as IntelliSense displays matching snippets' names.
4. Select the correct snippet (or keep typing until the entire snippet's name is selected).
5. Press the Tab key twice to insert the snippet at the cursor location.

```
static void Main(string[] args)
{
    Azure
}
```

AzureTrainingKitAsyncWorkloadHandling
AzureTrainingKitIntro
AzureTrainingKitRoleCommunication
AzureTrainingKitServiceBus

Start typing the snippet name

```
static void Main(string[] args)
{
    AzureTrainingKitServiceBus
}
```

Press Tab to select the highlighted snippet

```
static void Main(string[] args)
{
    request.Headers.Add("$accountKey", accountKey);
    request.Headers.Add("$uniqueUserID", uniqueUserId);
}
```

Press Tab again and the snippet will expand

To add a code snippet using the mouse (C#, Visual Basic and XML)

1. Right-click where you want to insert the code snippet.
2. Select **Insert Snippet** followed by **My Code Snippets**.
3. Pick the relevant snippet from the list, by clicking on it.

Right-click where you want to insert the code snippet and select Insert Snippet

Pick the relevant snippet from the list, by clicking on it

Appendix B: Installing Visual Studio Express 2012 for Web

You can install **Microsoft Visual Studio Express 2012 for Web** or another "Express" version using the **Microsoft Web Platform Installer**. The following instructions guide you through the steps required to install *Visual studio Express 2012 for Web* using *Microsoft Web Platform Installer*.

1. Go to https://go.microsoft.com/?linkid=9810169. Alternatively, if you already have installed Web Platform Installer, you can open it and search for the product "*Visual Studio Express 2012 for Web with Azure SDK*".

2. Click on **Install Now**. If you do not have **Web Platform Installer** you will be redirected to download and install it first.

3. Once **Web Platform Installer** is open, click **Install** to start the setup.

Install Visual Studio Express

4. Read all the products' licenses and terms and click **I Accept** to continue.

Accepting the license terms

5. Wait until the downloading and installation process completes.

Installation progress

6. When the installation completes, click **Finish**.

Installation completed

7. Click **Exit** to close Web Platform Installer.

8. To open Visual Studio Express for Web, go to the **Start** screen and start writing "**VS Express**", then click on the **VS Express for Web** tile.

VS Express for Web tile

Appendix C: Publishing an ASP.NET MVC 4 Application using Web Deploy

This appendix will show you how to create a new web site from the Azure Portal and publish the application you obtained by following the lab, taking advantage of the Web Deploy publishing feature provided by Azure.

Task 1 - Creating a New Web Site from the Azure Portal

1. Go to the Azure Management Portal and sign in using the Microsoft credentials associated with your subscription.

> **NOTE**
> With Azure you can host 10 ASP.NET Web Sites for free and then scale as your traffic grows. You can sign up here.

Log on to Portal

2. Click **New** on the command bar.

Creating a new Web Site

3. Click **Compute | Web Site**. Then select **Quick Create** option. Provide an available URL for the new web site and click **Create Web Site**.

> **NOTE**
>
> Azure is the host for a web application running in the cloud that you can control and manage. The Quick Create option allows you to deploy a completed web application to the Azure from outside the portal. It does not include steps for setting up a database.

Creating a new Web Site using Quick Create

4. Wait until the new **Web Site** is created.
5. Once the Web Site is created click the link under the **URL** column. Check that the new Web Site is working.

Browsing to the new web site

Web site running

6. Go back to the portal and click the name of the web site under the **Name** column to display the management pages.

Opening the Web Site management pages

7. In the **Dashboard** page, under the **quick glance** section, click the **Download publish profile** link.

> **NOTE**
>
> The *publish profile* contains all of the information required to publish a web application to a Azure for each enabled publication method. The publish profile contains the URLs, user credentials and database strings required to connect to and authenticate against each of the endpoints for which a publication method is enabled. **Microsoft WebMatrix 2**, **Microsoft Visual Studio Express for Web** and **Microsoft Visual Studio 2012** support reading publish profiles to automate configuration of these programs for publishing web applications to Azure.

Downloading the Web Site publish profile

8. Download the publish profile file to a known location. Further in this exercise you will see how to use this file to publish a web application to Azure from Visual Studio.

Saving the publish profile file

Task 2 - Configuring the Database Server

If your application makes use of SQL Server databases you will need to create a SQL Database server. If you want to deploy a simple application that does not use SQL Server you might skip this task.

1. You will need a SQL Database server for storing the application database. You can view the SQL Database servers from your subscription in the Azure Management portal at **Sql Databases | Servers | Server's Dashboard**. If you do not have a server created, you can create one using the **Add** button on the command bar. Take note of the **server name and URL, administrator login name and password**, as you will use them in the next tasks. Do not create the database yet, as it will be created in a later stage.

SQL Database Server Dashboard

2. In the next task you will test the database connection from Visual Studio, for that reason you need to include your local IP address in the server's list of **Allowed IP Addresses**. To do that, click **Configure**, select the IP address from **Current Client IP Address** and paste it on the **Start IP Address** and **End IP Address** text boxes and click the ✔ button.

Adding Client IP Address

3. Once the **Client IP Address** is added to the allowed IP addresses list, click on **Save** to confirm the changes.

Confirm Changes

Task 3 - Publishing an ASP.NET MVC 4 Application using Web Deploy

1. Go back to the ASP.NET MVC 4 solution. In the **Solution Explorer**, right-click the web site project and select **Publish**.

Publishing the web site

2. Import the publish profile you saved in the first task.

Importing publish profile

3. Click **Validate Connection**. Once Validation is complete click **Next**.

> **NOTE**
>
> Validation is complete once you see a green checkmark appear next to the Validate Connection button.

Validating connection

4. In the **Settings** page, under the **Databases** section, click the button next to your database connection's textbox (i.e. **DefaultConnection**).

Web deploy configuration

5. Configure the database connection as follows:

   - In the **Server name** type your SQL Database server URL using the *tcp:* prefix.
   - In **User name** type your server administrator login name.
   - In **Password** type your server administrator login password.
   - Type a new database name, for example: *MVC4SampleDB*.

Configuring destination connection string

6. Then click **OK**. When prompted to create the database click **Yes**.

Creating the database

7. The connection string you will use to connect to SQL Database in Windows Azure is shown within Default Connection textbox. Then click **Next**.

Connection string pointing to SQL Database

8. In the **Preview** page, click **Publish**.

Publishing the web application

9. Once the publishing process finishes, your default browser will open the published web site.

Application published to Azure

Web API Samples List

2/20/2020 • 6 minutes to read • Edit Online

HttpClient Samples

Bing Translate Sample | VS 2012 source

Shows how to call the Microsoft Translator service using the **HttpClient** class. The Microsoft Translator service API requires an OAuth token, which the application obtains by sending a request to the Azure token server for each request to the translator service. The result from the token server is fed into the request sent to the translation service. Before running this sample, you must obtain an application key from Azure Marketplace and fill in the information in the AccessTokenMessageHandler sample class.

Google Maps Sample | detailed description | VS 2012 source

Uses **HttpClient** to download a map of Redmond, WA from Google Maps API, saves it as a local file, and opens the default image viewer.

Twitter Client Sample | detailed description | VS 2012 source

Shows how to write a simple Twitter client using **HttpClient**. The sample uses an **HttpMessageHandler** to insert OAuth authentication information into the outgoing **HttpRequestMessage**. The result from Twitter is read using JSON.NET. Before running this sample, you must obtain an application key from Twitter, and fill in the information in the OAuthMessageHandler sample class.

World Bank Sample | detailed description | VS 2010 source | VS 2012 source

Shows how to retrieve data from the World Bank data site, using JSON.NET to parse the result.

Web API Samples

Getting Started with ASP.NET Web API | VS 2012 source

Shows how to create a basic web API that supports HTTP GET requests. Contains the source code for the tutorial Your First ASP.NET Web API.

ASP.NET Web API JavaScript Scenarios – Comments | VS 2012 source

Shows how to use ASP.NET Web API to build web APIs that support browser clients and can be easily called using jQuery.

Contact Manager | VS 2010 source

This sample uses ASP.NET Web API to build a simple contact manager application. The application consists of a contact manager web API that is used by an ASP.NET MVC application and a Windows Phone application to display and manage a list of contacts.

Batching Sample | detailed description | VS 2012 source

Shows how to implement HTTP batching within ASP.NET. The batching consists of putting multiple HTTP requests within a single MIME multipart entity body, which is then sent to the server as an HTTP POST. The requests are processed individually, and the responses are put into another MIME multipart entity body, which is returned to the client.

Content Controller Sample | detailed description | VS 2010 source | VS 2012 source

Shows how to read and write request and response entities asynchronously using streams. The sample controller has two actions: a PUT action that reads the request entity body asynchronously and stores it in a local file, and a GET action that returns the contents of the local file.

Custom Assembly Resolver Sample | VS 2012 source

Shows how to modify ASP.NET Web API to support discovery of controllers from a dynamically loaded library assembly. The sample implements a custom **IAssembliesResolver** which calls the default implementation and then adds the library assembly to the default results.

Custom Media Type Formatter Sample | detailed description | VS 2010 source

Shows how to create a custom media type formatter using the **BufferedMediaTypeFormatter** base class. This base class is intended for formatters which primarily use synchronous read and write operations. In addition to showing the media type formatter, the sample shows how to hook it up by registering it as part of the **HttpConfiguration** for your application. Note that it is also possible to use the **MediaTypeFormatter** base class directly, for formatters which primarily use asynchronous read and write operations.

Custom Parameter Binding Sample | detailed description | VS 2010 source

Shows how to customize the parameter binding process, which is the process that determines how information from a request is bound to action parameters. In this sample, the Home controller has four actions:

1. BindPrincipal shows how to bind an IPrincipal parameter from a custom generic principal, not from an HTTP GET message;
2. BindCustomComplexTypeFromUriOrBody shows how to bind a complex-type parameter, which could come either from the message body or from the request URI of an HTTP POST message;
3. BindCustomComplexTypeFromUriWithRenamedProperty shows how to bind a complex-type parameter with a renamed property which comes from the request URI of an HTTP POST message;
4. PostMultipleParametersFromBody shows how to bind multiple parameters from the body for a POST message;

File Upload Sample | detailed description | VS 2012 source

Shows how to upload files to an **ApiController** using MIME Multipart File Upload, and how to set up progress notifications with **HttpClient** using **ProgressNotificationHandler**. The controller reads the contents of an HTML file upload asynchronously and writes one or more body parts to a local file. The response contains information about the uploaded file (or files).

File Upload to Azure Blob Store Sample | detailed description | VS 2012 source

This sample is similar to the File Upload Sample, but instead of saving the uploaded files on local disk, it asynchronously uploads the files to Azure Blob Store using Windows Azure SDK for .NET. It also provides a mechanism for listing the blobs currently present in an Azure Blob Storage Container. You can try out the sample running against **Azure Storage Emulator** that comes with the Azure SDK. If you have an Azure Storage Account, you can run against the real storage service as well.

Http Message Handler Pipeline Sample | detailed description | VS 2010 source

Shows how to wire up **HttpMessageHandler** instances on both the client (**HttpClient**) and server (ASP.NET Web API). In the sample, the same handler is used on both the client and server. While it is rare that the exact same handler would run in both places, the object model is the same on client and server side.

JSON Upload Sample | VS 2012 source

Shows how to upload and download JSON to and from an **ApiController**. The sample uses a minimal **ApiController** and accesses it using **HttpClient**.

Mashup Sample | detailed description | VS 2012 source

Shows how to access multiple remote sites asynchronously from within an **ApiController** action. Each time the action is hit, the requests are performed asynchronously, so that no threads are blocked.

Memory Tracing Sample | detailed description | VS 2010 source

This sample project creates a Nuget package that will install a custom in-memory trace writer into ASP.NET Web API applications.

MongoDB Sample | detailed description | VS 2012 source

Shows how to use MongoDB as the persistent store for an **ApiController**, using a repository pattern.

Response Body Processor Sample | VS 2012 source

Shows how to copy a response entity (that is, an HTTP response body) to a local file before it is transmitted to the client, and perform additional processing on that file asynchronously. The sample implements an **HttpMessageHandler** that wraps the response entity with one that both writes itself to the output as normal and to a local file.

Upload XDocument Sample | detailed description | VS 2012 source

Shows how to upload an XDocument to an **ApiController** using **PushStreamContent** and **HttpClient**.

Validation Sample | VS 2010 source

Shows how you can use validation attributes on your models in ASP.NET WebAPI to validate the contents of the HTTP request. Demonstrates how to mark properties as required, how to use both framework-defined and custom validation attributes to annotate your model, and how to return error responses for invalid model states.

Web Form Sample | detailed description | VS 2010 source

Shows an ApiController added to a Web Forms project.

RestBugs Sample

RestBugs is a simple bug tracking application that shows how to use ASP.NET Web API and the new HTTP Client library to create a hypermedia-driven system. The sample includes both client and server implementations, using ASP.NET Web API. The server uses a custom Razor formatter to generate resource representations. The sample also provides a node.js server to illustrate the benefits that come from using a hypermedia design to decouple clients and servers.

ASP.NET Web Pages

4/10/2020 • 2 minutes to read • Edit Online

NOTE

WebMatrix is no longer recommended as an integrated development environment for ASP.NET Web Pages. Use Visual Studio or Visual Studio Code.

Programming ASP.NET Web Pages (Razor) Using Visual Studio

4/10/2020 • 5 minutes to read • Edit Online

by Tom FitzMacken

This article explains how you can use Visual Studio or Visual Web Developer Express to program ASP.NET Web Pages (Razor) websites.

What you'll learn

- What you need to install (if anything) to work with ASP.NET Web Pages in your version of Visual Studio.
- How to add support for ASP.NET Web Pages to Visual Web Developer 2010 Express.
- How to use features in Visual Studio to work with ASP.NET Razor pages, including IntelliSense and the debugger.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3
- Visual Studio 2013
- WebMatrix 3

This tutorial also works with ASP.NET Web Pages 2, Visual Studio 2012, Visual Studio 2010, and WebMatrix 2.

You can program ASP.NET Web pages with Razor syntax using WebMatrix or many other code editors. You can also use Microsoft Visual Studio which is a full-featured integrated development environment (IDE) that provides a powerful set of tools for creating many types of applications (not just websites). To work with ASP.NET Razor pages, you can use Visual Studio 2017.

Two particularly useful features that Visual Studio provides for programming with ASP.NET Razor web pages are:

- *IntelliSense*. The IntelliSense feature built into Visual Studio is more comprehensive than IntelliSense in WebMatrix.
- *Debugger*. The debugger lets you troubleshoot your code by stopping a program while it's running, examining variables, and stepping through the code line by line.

Using Visual Studio with Different Versions of ASP.NET Web Pages

To develop ASP.NET web apps in Visual Studio 2017, install the **ASP.NET and web development** workload.

Visual Studio 2012 and Visual Studio 2013 include support for ASP.NET Web Pages. (The packages that are required in order to support ASP.NET Web Pages are installed when you install Visual Studio.)

Visual Studio 2010 does not include support by default for ASP.NET Web Pages. To use ASP.NET Web Pages with Visual Studio 2010, you must install the ASP.NET MVC package. To get ASP.NET Web Pages 2, you install ASP.NET MVC 4.

The following table summarizes the support for ASP.NET Web Pages in different versions of Visual Studio.

	VISUAL STUDIO 2010	VISUAL STUDIO 2012	VISUAL STUDIO 2013
ASP.NET Web Pages 2	Install ASP.NET MVC 4	(Included)	(Included)
ASP.NET Web Pages 3		Update to ASP.NET Web Pages 3 through NuGet	(Included)

To work with Visual Studio 2010, see Installing Support for ASP.NET Web Pages in Visual Studio 2010.

Launching Visual Studio from WebMatrix

If you have started a project in WebMatrix and want to switch to Visual Studio, WebMatrix provides a button to easily open the project in Visual Studio. You must have Visual Studio installed on your computer for this button to be enabled. The following image shows the button in WebMatrix.

When you click the button, the project is opened in Visual Studio. You can switch back and forth between WebMatrix and Visual Studio without any problems. You will be notified if any files have changed in the other environment and need to be reloaded to get the latest changes.

Creating ASP.NET Razor Site in Visual Studio

To create an ASP.NET Razor website in Visual Studio:

1. Open Visual Studio.
2. In the **File** menu, click **New Web Site**.

3. In the **New Web Site** dialog box, select the language to use (Visual C# or Visual Basic).
4. Select the **ASP.NET Web Site (Razor)** template.

5. Click **OK**.

Your new project exists and is populated with some default web pages to help you get started.

Using IntelliSense

Now that you've created a site, you can see how IntelliSense works in Visual Studio.

1. In the website you just created, open the *Default.cshtml* page.

2. After the `<h3>` tags in the page, type `@ServerInfo.` (including the dot). Notice how IntelliSense displays the available methods for the `ServerInfo` helper in a drop-down list.

3. Select the `GetHtml` method from the list and then press Enter. IntelliSense automatically fills in the method. (As with any method in C#, you must add `()` characters after the method.) The completed code for the `GetHtml` method looks like the following example:

```
@ServerInfo.GetHtml()
```

4. Press Ctrl+F5 to run the page. This is what the page looks like when displayed in a browser:

5. Close the browser.

Using the Debugger

1. At the top of the *Default.cshtml* page, after the line that begins with `Page.Title`, add the following line of code:

```
var myTime = DateTime.Now.TimeOfDay;
```

2. In the gray margin of the editor to the left of the code, click next to this new line in order to add a *breakpoint*. A breakpoint is a marker that tells the debugger to stop running the program at that point so you can see what's happening.

```
@{
    Layout = "~/_SiteLayout.cshtml";
    Page.Title = "Home Page";
    var myTime = DateTime.Now.TimeOfDay;
}
```

3. Remove the call to the `ServerInfo.GetHtml` method, and add a call to the `@myTime` variable in its place. This call displays the current time value that's returned by the new line of code.

4. Press F5 to run the page in the debugger. The page stops on the breakpoint that you set. The following image shows what the page looks like in the editor with the breakpoint (in yellow).

```
@{
    Layout = "~/_SiteLayout.cshtml";
    Page.Title = "Home Page";
    var myTime = DateTime.Now.TimeOfDay;
}
```

5. In the Debug toolbar, click the **Step Into** button (or press F11) to run the next line of code. Each time you click this button, you advance the execution to the next line of code.

6. Examine the value of the `myTime` variable by holding your mouse pointer over it or by inspecting the values displayed in the **Locals** and **Call Stack** windows. Visual Studio display the value of the variable.

```
@{
    Layout = "~/_SiteLayout.cshtml";
    Page.Title = "Home Page";
    var myTime = DateTime.Now.TimeOfDay;
}
```

myTime {14:54:10.4713083}

7. When you're done examining the variable and stepping through code, press F5 to continue running the page without stopping at each line. When you've finished stepping through all the code, the browser displays the page.

To learn more about the debugger and about how to debug code in Visual Studio, see Walkthrough: Debugging Web Pages in Visual Web Developer.

Using Razor in ASP.NET MVC projects with Visual Studio

The Razor syntax is also used extensively in ASP.NET MVC projects. MVC is a powerful, patterns-based way to build dynamic websites. If your ASP.NET Web Pages site becomes difficult to maintain, you might want to consider converting it to an ASP.NET MVC application. For an example of creating an MVC application, see Getting Started with ASP.NET MVC 5.

Installing Support for ASP.NET Web Pages in Visual Studio 2010

This section shows how to install Visual Web Developer Express 2010 and the ASP.NET Web Pages Tools for Visual Studio.

1. If you don't already have the Web Platform Installer, download it from the following URL:

   https://www.microsoft.com/web/downloads/platform.aspx

2. Run the Web Platform Installer.

3. Click the **Products** tab.

4. Search for **ASP.NET MVC 4** (for ASP.NET Web Pages 2) and then click **Add**. These products include Visual Studio tools for building ASP.NET Razor websites.

5. Click **Install** to complete the installation.

Introduction to ASP.NET Web Programming Using the Razor Syntax (C#)

2/20/2020 • 40 minutes to read • Edit Online

by Tom FitzMacken

This article gives you an overview of programming with ASP.NET Web Pages using the Razor syntax. ASP.NET is Microsoft's technology for running dynamic web pages on web servers. This articles focuses on using the C# programming language.

What you'll learn:

- The top 8 programming tips for getting started with programming ASP.NET Web Pages using Razor syntax.
- Basic programming concepts you'll need.
- What ASP.NET server code and the Razor syntax is all about.

Software versions

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

The Top 8 Programming Tips

This section lists a few tips that you absolutely need to know as you start writing ASP.NET server code using the Razor syntax.

> **NOTE**
>
> The Razor syntax is based on the C# programming language, and that's the language that's used most often with ASP.NET Web Pages. However, the Razor syntax also supports the Visual Basic language, and everything you see you can also do in Visual Basic. For details, see the appendix Visual Basic Language and Syntax.

You can find more details about most of these programming techniques later in the article.

1. You add code to a page using the @ character

The `@` character starts inline expressions, single statement blocks, and multi-statement blocks:

```
<!-- Single statement blocks  -->
@{ var total = 7; }
@{ var myMessage = "Hello World"; }

<!-- Inline expressions -->
<p>The value of your account is: @total </p>
<p>The value of myMessage is: @myMessage</p>

<!-- Multi-statement block -->
@{
    var greeting = "Welcome to our site!";
    var weekDay = DateTime.Now.DayOfWeek;
    var greetingMessage = greeting + " Today is: " + weekDay;
}
<p>The greeting is: @greetingMessage</p>
```

This is what these statements look like when the page runs in a browser:

TIP

HTML Encoding

When you display content in a page using the `@` character, as in the preceding examples, ASP.NET HTML-encodes the output. This replaces reserved HTML characters (such as `<` and `>` and `&`) with codes that enable the characters to be displayed as characters in a web page instead of being interpreted as HTML tags or entities. Without HTML encoding, the output from your server code might not display correctly, and could expose a page to security risks.

If your goal is to output HTML markup that renders tags as markup (for example `<p></p>` for a paragraph or `<em></em>` to emphasize text), see the section Combining Text, Markup, and Code in Code Blocks later in this article.

You can read more about HTML encoding in Working with Forms.

2. You enclose code blocks in braces

A *code block* includes one or more code statements and is enclosed in braces.

```
<!-- Single statement block.  -->
@{ var theMonth = DateTime.Now.Month; }
<p>The numeric value of the current month: @theMonth</p>

<!-- Multi-statement block. -->
@{
    var outsideTemp = 79;
    var weatherMessage = "Hello, it is " + outsideTemp + " degrees.";
}
<p>Today's weather: @weatherMessage</p>
```

The result displayed in a browser:

3. Inside a block, you end each code statement with a semicolon

Inside a code block, each complete code statement must end with a semicolon. Inline expressions don't end with a semicolon.

```
<!-- Single-statement block -->
@{ var theMonth = DateTime.Now.Month; }

<!-- Multi-statement block -->
@{
    var outsideTemp = 79;
    var weatherMessage = "Hello, it is " + outsideTemp + " degrees.";
}

<!-- Inline expression, so no semicolon -->
<p>Today's weather: @weatherMessage</p>
```

4. You use variables to store values

You can store values in a *variable*, including strings, numbers, and dates, etc. You create a new variable using the `var` keyword. You can insert variable values directly in a page using `@`.

```
<!-- Storing a string -->
@{ var welcomeMessage = "Welcome, new members!"; }
<p>@welcomeMessage</p>

<!-- Storing a date -->
@{ var year = DateTime.Now.Year; }

<!-- Displaying a variable -->
<p>Welcome to our new members who joined in @year!</p>
```

The result displayed in a browser:

5. You enclose literal string values in double quotation marks

A *string* is a sequence of characters that are treated as text. To specify a string, you enclose it in double quotation marks:

```
@{ var myString = "This is a string literal"; }
```

If the string that you want to display contains a backslash character (`\`) or double quotation marks (`"`), use a *verbatim string literal* that's prefixed with the `@` operator. (In C#, the \ character has special meaning unless you use a verbatim string literal.)

```
<!-- Embedding a backslash in a string -->
@{ var myFilePath = @"C:\MyFolder\"; }
<p>The path is: @myFilePath</p>
```

To embed double quotation marks, use a verbatim string literal and repeat the quotation marks:

```
<!-- Embedding double quotation marks in a string -->
@{ var myQuote = @"The person said: ""Hello, today is Monday."""; }
<p>@myQuote</p>
```

Here's the result of using both of these examples in a page:

> **NOTE**
> Notice that the `@` character is used both to mark verbatim string literals in C# and to mark code in ASP.NET pages.

6. Code is case sensitive

In C#, keywords (like `var`, `true`, and `if`) and variable names are case sensitive. The following lines of code create two different variables, `lastName` and `LastName.`

```
@{
    var lastName = "Smith";
    var LastName = "Jones";
}
```

If you declare a variable as `var lastName = "Smith";` and try to reference that variable in your page as `@LastName`, you would get the value `"Jones"` instead of `"Smith"`.

> **NOTE**
> In Visual Basic, keywords and variables are *not* case sensitive.

7. Much of your coding involves objects

An *object* represents a thing that you can program with — a page, a text box, a file, an image, a web request, an email message, a customer record (database row), etc. Objects have properties that describe their characteristics and that you can read or change — a text box object has a `Text` property (among others), a request object has a `Url` property, an email message has a `From` property, and a customer object has a `FirstName` property. Objects also have methods that are the "verbs" they can perform. Examples include a file object's `Save` method, an image object's `Rotate` method, and an email object's `Send` method.

You'll often work with the `Request` object, which gives you information like the values of text boxes (form fields) on the page, what type of browser made the request, the URL of the page, the user identity, etc. The following example shows how to access properties of the `Request` object and how to call the `MapPath` method of the `Request` object, which gives you the absolute path of the page on the server:

```
<table border="1">
<tr>
    <td>Requested URL</td>
    <td>Relative Path</td>
    <td>Full Path</td>
    <td>HTTP Request Type</td>
</tr>
<tr>
    <td>@Request.Url</td>
    <td>@Request.FilePath</td>
    <td>@Request.MapPath(Request.FilePath)</td>
    <td>@Request.RequestType</td>
</tr>
</table>
```

The result displayed in a browser:

8. You can write code that makes decisions

A key feature of dynamic web pages is that you can determine what to do based on conditions. The most common way to do this is with the `if` statement (and optional `else` statement).

```
@{
   var result = "";
   if(IsPost)
   {
      result = "This page was posted using the Submit button.";
   }
   else
   {
      result = "This was the first request for this page.";
   }
}

<!DOCTYPE html>
<html>
    <head>
        <title></title>
    </head>
<body>
<form method="POST" action="" >
  <input type="Submit" name="Submit" value="Submit"/>
  <p>@result</p>
</form>
</body>
</html>
```

The statement `if(IsPost)` is a shorthand way of writing `if(IsPost == true)`. Along with `if` statements, there are a variety of ways to test conditions, repeat blocks of code, and so on, which are described later in this article.

The result displayed in a browser (after clicking **Submit**):

TIP

HTTP GET and POST Methods and the IsPost Property

The protocol used for web pages (HTTP) supports a very limited number of methods (verbs) that are used to make requests to the server. The two most common ones are GET, which is used to read a page, and POST, which is used to submit a page. In general, the first time a user requests a page, the page is requested using GET. If the user fills in a form and then clicks a submit button, the browser makes a POST request to the server.

In web programming, it's often useful to know whether a page is being requested as a GET or as a POST so that you know how to process the page. In ASP.NET Web Pages, you can use the `IsPost` property to see whether a request is a GET or a POST. If the request is a POST, the `IsPost` property will return true, and you can do things like read the values of text boxes on a form. Many examples you'll see show you how to process the page differently depending on the value of `IsPost`.

A Simple Code Example

This procedure shows you how to create a page that illustrates basic programming techniques. In the example, you create a page that lets users enter two numbers, then it adds them and displays the result.

1. In your editor, create a new file and name it *AddNumbers.cshtml*.

2. Copy the following code and markup into the page, replacing anything already in the page.

```
@{
    var total = 0;
    var totalMessage = "";
    if(IsPost) {

        // Retrieve the numbers that the user entered.
        var num1 = Request["text1"];
        var num2 = Request["text2"];

        // Convert the entered strings into integers numbers and add.
        total = num1.AsInt() + num2.AsInt();
        totalMessage = "Total = " + total;
    }
}

<!DOCTYPE html>
<html lang="en">
  <head>
    <title>Add Numbers</title>
    <meta charset="utf-8" />
    <style type="text/css">
      body {background-color: beige; font-family: Verdana, Arial;
            margin: 50px; }
      form {padding: 10px; border-style: solid; width: 250px;}
    </style>
  </head>
<body>
  <p>Enter two whole numbers and then click <strong>Add</strong>.</p>
  <form action="" method="post">
    <p><label for="text1">First Number:</label>
      <input type="text" name="text1" />
    </p>
    <p><label for="text2">Second Number:</label>
      <input type="text" name="text2" />
    </p>
    <p><input type="submit" value="Add" /></p>
  </form>

  <p>@totalMessage</p>

</body>
</html>
```

Here are some things for you to note:

- The `@` character starts the first block of code in the page, and it precedes the `totalMessage` variable that's embedded near the bottom of the page.
- The block at the top of the page is enclosed in braces.
- In the block at the top, all lines end with a semicolon.
- The variables `total`, `num1`, `num2`, and `totalMessage` store several numbers and a string.
- The literal string value assigned to the `totalMessage` variable is in double quotation marks.
- Because the code is case-sensitive, when the `totalMessage` variable is used near the bottom of the page, its name must match the variable at the top exactly.
- The expression `num1.AsInt() + num2.AsInt()` shows how to work with objects and methods. The `AsInt` method on each variable converts the string entered by a user to a number (an integer) so that you can perform arithmetic on it.
- The `<form>` tag includes a `method="post"` attribute. This specifies that when the user clicks **Add**, the page will be sent to the server using the HTTP POST method. When the page is submitted, the `if(IsPost)` test evaluates to true and the conditional code runs, displaying the result of adding the

numbers.

3. Save the page and run it in a browser. (Make sure the page is selected in the **Files** workspace before you run it.) Enter two whole numbers and then click the **Add** button.

Basic Programming Concepts

This article provides you with an overview of ASP.NET web programming. It isn't an exhaustive examination, just a quick tour through the programming concepts you'll use most often. Even so, it covers almost everything you'll need to get started with ASP.NET Web Pages.

But first, a little technical background.

The Razor Syntax, Server Code, and ASP.NET

Razor syntax is a simple programming syntax for embedding server-based code in a web page. In a web page that uses the Razor syntax, there are two kinds of content: client content and server code. Client content is the stuff you're used to in web pages: HTML markup (elements), style information such as CSS, maybe some client script such as JavaScript, and plain text.

Razor syntax lets you add server code to this client content. If there's server code in the page, the server runs that code first, before it sends the page to the browser. By running on the server, the code can perform tasks that can be a lot more complex to do using client content alone, like accessing server-based databases. Most importantly, server code can dynamically create client content — it can generate HTML markup or other content on the fly and then send it to the browser along with any static HTML that the page might contain. From the browser's perspective, client content that's generated by your server code is no different than any other client content. As you've already seen, the server code that's required is quite simple.

ASP.NET web pages that include the Razor syntax have a special file extension (*.cshtml* or *.vbhtml*). The server recognizes these extensions, runs the code that's marked with Razor syntax, and then sends the page to the browser.

Where does ASP.NET fit in?

Razor syntax is based on a technology from Microsoft called ASP.NET, which in turn is based on the Microsoft .NET Framework. The.NET Framework is a big, comprehensive programming framework from Microsoft for developing virtually any type of computer application. ASP.NET is the part of the .NET Framework that's specifically designed for creating web applications. Developers have used ASP.NET to create many of the largest and highest-traffic websites in the world. (Any time you see the file-name extension *.aspx* as part of the URL in a site, you'll know that the site was written using ASP.NET.)

The Razor syntax gives you all the power of ASP.NET, but using a simplified syntax that's easier to learn if you're a beginner and that makes you more productive if you're an expert. Even though this syntax is simple to use, its family relationship to ASP.NET and the .NET Framework means that as your websites become more sophisticated, you have the power of the larger frameworks available to you.

TIP

Classes and Instances

ASP.NET server code uses objects, which are in turn built on the idea of classes. The class is the definition or template for an object. For example, an application might contain a `Customer` class that defines the properties and methods that any customer object needs.

When the application needs to work with actual customer information, it creates an instance of (or *instantiates*) a customer object. Each individual customer is a separate instance of the `Customer` class. Every instance supports the same properties and methods, but the property values for each instance are typically different, because each customer object is unique. In one customer object, the `LastName` property might be "Smith"; in another customer object, the `LastName` property might be "Jones."

Similarly, any individual web page in your site is a `Page` object that's an instance of the `Page` class. A button on the page is a `Button` object that is an instance of the `Button` class, and so on. Each instance has its own characteristics, but they all are based on what's specified in the object's class definition.

Basic Syntax

Earlier you saw a basic example of how to create an ASP.NET Web Pages page, and how you can add server code to HTML markup. Here you'll learn the basics of writing ASP.NET server code using the Razor syntax — that is, the programming language rules.

If you're experienced with programming (especially if you've used C, C++, C#, Visual Basic, or JavaScript), much of what you read here will be familiar. You'll probably need to familiarize yourself only with how server code is added to markup in *.cshtml* files.

Combining Text, Markup, and Code in Code Blocks

In server code blocks, you often want to output text or markup (or both) to the page. If a server code block contains text that's not code and that instead should be rendered as is, ASP.NET needs to be able to distinguish that text from code. There are several ways to do this.

- Enclose the text in an HTML element like `<p></p>` or `<em></em>`:

```
@if(IsPost) {
    // This line has all content between matched <p> tags.
    <p>Hello, the time is @DateTime.Now and this page is a postback!</p>
} else {
    // All content between matched tags, followed by server code.
    <p>Hello <em>stranger</em>, today is: <br /> </p>  @DateTime.Now
}
```

The HTML element can include text, additional HTML elements, and server-code expressions. When ASP.NET sees the opening HTML tag (for example, `<p>`), it renders everything including the element and its content as is to the browser, resolving server-code expressions as it goes.

- Use the `@:` operator or the `<text>` element. The `@:` outputs a single line of content containing plain text or unmatched HTML tags; the `<text>` element encloses multiple lines to output. These options are useful when you don't want to render an HTML element as part of the output.

```
@if(IsPost) {
    // Plain text followed by an unmatched HTML tag and server code.
    @: The time is: <br /> @DateTime.Now
    <br/>
    // Server code and then plain text, matched tags, and more text.
    @DateTime.Now @:is the <em>current</em> time.
}
```

If you want to output multiple lines of text or unmatched HTML tags, you can precede each line with `@:`, or you can enclose the line in a `<text>` element. Like the `@:` operator, `<text>` tags are used by ASP.NET to identify text content and are never rendered in the page output.

```
@if(IsPost) {
    // Repeat the previous example, but use <text> tags.
    <text>
    The time is: <br /> @DateTime.Now
    <br/>
    @DateTime.Now is the <em>current</em> time.
    </text>
}

@{
    var minTemp = 75;
    <text>It is the month of @DateTime.Now.ToString("MMMM"), and
    it's a <em>great</em> day! <br /><p>You can go swimming if it's at
    least @minTemp degrees. </p></text>
}
```

The first example repeats the previous example but uses a single pair of `<text>` tags to enclose the text to render. In the second example, the `<text>` and `</text>` tags enclose three lines, all of which have some uncontained text and unmatched HTML tags (`<br />`), along with server code and matched HTML tags. Again, you could also precede each line individually with the `@:` operator; either way works.

> **NOTE**
>
> When you output text as shown in this section — using an HTML element, the `@:` operator, or the `<text>` element — ASP.NET doesn't HTML-encode the output. (As noted earlier, ASP.NET does encode the output of server code expressions and server code blocks that are preceded by `@`, except in the special cases noted in this section.)

Whitespace

Extra spaces in a statement (and outside of a string literal) don't affect the statement:

```
@{ var lastName =    "Smith"; }
```

A line break in a statement has no effect on the statement, and you can wrap statements for readability. The following statements are the same:

```
@{ var theName =
"Smith"; }

@{
    var
    personName
    =
    "Smith"
    ;
}
```

However, you can't wrap a line in the middle of a string literal. The following example doesn't work:

```
@{ var test = "This is a long
    string"; }  // Does not work!
```

To combine a long string that wraps to multiple lines like the above code, there are two options. You can use the concatenation operator (`+`), which you'll see later in this article. You can also use the `@` character to create a verbatim string literal, as you saw earlier in this article. You can break verbatim string literals across lines:

```
@{ var longString = @"This is a
    long
    string";
}
```

Code (and Markup) Comments

Comments let you leave notes for yourself or others. They also allow you to disable (*comment out*) a section of code or markup that you don't want to run but want to keep in your page for the time being.

There's different commenting syntax for Razor code and for HTML markup. As with all Razor code, Razor comments are processed (and then removed) on the server before the page is sent to the browser. Therefore, the Razor commenting syntax lets you put comments into the code (or even into the markup) that you can see when you edit the file, but that users don't see, even in the page source.

For ASP.NET Razor comments, you start the comment with `@*` and end it with `*@`. The comment can be on one line or multiple lines:

```
@*  A one-line code comment. *@

@*
    This is a multiline code comment.
    It can continue for any number of lines.
*@
```

Here is a comment within a code block:

```
@{
    @* This is a comment. *@
    var theVar = 17;
}
```

Here is the same block of code, with the line of code commented out so that it won't run:

```
@{
    @* This is a comment. *@
    @* var theVar = 17;  *@
}
```

Inside a code block, as an alternative to using Razor comment syntax, you can use the commenting syntax of the programming language you're using, such as C#:

```
@{
    // This is a comment.
    var myVar = 17;
    /* This is a multi-line comment
    that uses C# commenting syntax. */
}
```

In C#, single-line comments are preceded by the `//` characters, and multi-line comments begin with `/*` and end with `*/`. (As with Razor comments, C# comments are not rendered to the browser.)

For markup, as you probably know, you can create an HTML comment:

```
<!-- This is a comment.  -->
```

HTML comments start with `<!--` characters and end with `-->`. You can use HTML comments to surround not only text, but also any HTML markup that you may want to keep in the page but don't want to render. This HTML comment will hide the entire content of the tags and the text they contain:

```
<!-- <p>This is my paragraph.</p>  -->
```

Unlike Razor comments, HTML comments *are* rendered to the page and the user can see them by viewing the page source.

Razor has limitations on nested blocks of C#. For more information see Named C# Variables and Nested Blocks Generate Broken Code

Variables

A variable is a named object that you use to store data. You can name variables anything, but the name must begin with an alphabetic character and it cannot contain whitespace or reserved characters.

Variables and Data Types

A variable can have a specific data type, which indicates what kind of data is stored in the variable. You can have string variables that store string values (like "Hello world"), integer variables that store whole-number values (like 3 or 79), and date variables that store date values in a variety of formats (like 4/12/2012 or March 2009). And there are many other data types you can use.

However, you generally don't have to specify a type for a variable. Most of the time, ASP.NET can figure out the type based on how the data in the variable is being used. (Occasionally you must specify a type; you'll see

examples where this is true.)

You declare a variable using the `var` keyword (if you don't want to specify a type) or by using the name of the type:

```
@{
    // Assigning a string to a variable.
    var greeting = "Welcome!";

    // Assigning a number to a variable.
    var theCount = 3;

    // Assigning an expression to a variable.
    var monthlyTotal = theCount + 5;

    // Assigning a date value to a variable.
    var today = DateTime.Today;

    // Assigning the current page's URL to a variable.
    var myPath = this.Request.Url;

    // Declaring variables using explicit data types.
    string name = "Joe";
    int count = 5;
    DateTime tomorrow = DateTime.Now.AddDays(1);
}
```

The following example shows some typical uses of variables in a web page:

```
@{
    // Embedding the value of a variable into HTML markup.
    <p>@greeting, friends!</p>

    // Using variables as part of an inline expression.
    <p>The predicted annual total is: @( monthlyTotal * 12)</p>

    // Displaying the page URL with a variable.
    <p>The URL to this page is: @myPath</p>
}
```

If you combine the previous examples in a page, you see this displayed in a browser:

Converting and Testing Data Types

Although ASP.NET can usually determine a data type automatically, sometimes it can't. Therefore, you might need to help ASP.NET out by performing an explicit conversion. Even if you don't have to convert types, sometimes it's helpful to test to see what type of data you might be working with.

The most common case is that you have to convert a string to another type, such as to an integer or date. The following example shows a typical case where you must convert a string to a number.

```
@{
    var total = 0;

    if(IsPost) {
        // Retrieve the numbers that the user entered.
        var num1 = Request["text1"];
        var num2 = Request["text2"];
        // Convert the entered strings into integers numbers and add.
        total = num1.AsInt() + num2.AsInt();
    }
}
```

As a rule, user input comes to you as strings. Even if you've prompted users to enter a number, and even if they've entered a digit, when user input is submitted and you read it in code, the data is in string format. Therefore, you must convert the string to a number. In the example, if you try to perform arithmetic on the values without converting them, the following error results, because ASP.NET cannot add two strings:

Cannot implicitly convert type 'string' to 'int'.

To convert the values to integers, you call the `AsInt` method. If the conversion is successful, you can then add the numbers.

The following table lists some common conversion and test methods for variables.

Method

Description

Example

`AsInt(), IsInt()`

Converts a string that represents a whole number (like "593") to an integer.

```
var myIntNumber = 0;
var myStringNum = "539";
if(myStringNum.IsInt()==true){
    myIntNumber = myStringNum.AsInt();
}
```

`AsBool(), IsBool()`

Converts a string like "true" or "false" to a Boolean type.

```
var myStringBool = "True";
var myVar = myStringBool.AsBool();
```

`AsFloat(), IsFloat()`

Converts a string that has a decimal value like "1.3" or "7.439" to a floating-point number.

```
var myStringFloat = "41.432895";
var myFloatNum = myStringFloat.AsFloat();
```

`AsDecimal(), IsDecimal()`

Converts a string that has a decimal value like "1.3" or "7.439" to a decimal number. (In ASP.NET, a decimal

number is more precise than a floating-point number.)

```
var myStringDec = "10317.425";
var myDecNum = myStringDec.AsDecimal();
```

`AsDateTime(), IsDateTime()`

Converts a string that represents a date and time value to the ASP.NET `DateTime` type.

```
var myDateString = "12/27/2012";
var newDate = myDateString.AsDateTime();
```

`ToString()`

Converts any other data type to a string.

```
int num1 = 17;
int num2 = 76;
// myString is set to 1776
string myString = num1.ToString() +
  num2.ToString();
```

Operators

An operator is a keyword or character that tells ASP.NET what kind of command to perform in an expression. The C# language (and the Razor syntax that's based on it) supports many operators, but you only need to recognize a few to get started. The following table summarizes the most common operators.

Operator

Description

Examples

`+` `-` `*` `/`

Math operators used in numerical expressions.

```
@(5 + 13)
@{ var netWorth = 150000; }
@{ var newTotal = netWorth * 2; }
@(newTotal / 2)
```

`=`

Assignment. Assigns the value on the right side of a statement to the object on the left side.

```
var age = 17;
```

`==`

Equality. Returns `true` if the values are equal. (Notice the distinction between the `=` operator and the `==` operator.)

```
var myNum = 15;
if (myNum == 15) {
    // Do something.
}
```

`!=`

Inequality. Returns `true` if the values are not equal.

```
var theNum = 13;
if (theNum != 15) {
    // Do something.
}
```

`< > <= >=`

Less-than, greater-than, less-than-or-equal, and greater-than-or-equal.

```
if (2 < 3) {
    // Do something.
}
var currentCount = 12;
if(currentCount >= 12) {
    // Do something.
}
```

`+`

Concatenation, which is used to join strings. ASP.NET knows the difference between this operator and the addition operator based on the data type of the expression.

```
// The displayed result is "abcdef".
@("abc" + "def")
```

`+=` `-=`

The increment and decrement operators, which add and subtract 1 (respectively) from a variable.

```
int theCount = 0;
theCount += 1; // Adds 1 to count
```

`.`

Dot. Used to distinguish objects and their properties and methods.

```
var myUrl = Request.Url;
var count = Request["Count"].AsInt();
```

`()`

Parentheses. Used to group expressions and to pass parameters to methods.

```
@(3 + 7)
@Request.MapPath(Request.FilePath);
```

`[]`

Brackets. Used for accessing values in arrays or collections.

```
var income = Request["AnnualIncome"];
```

`!`

Not. Reverses a `true` value to `false` and vice versa. Typically used as a shorthand way to test for `false` (that is, for not `true`).

```
bool taskCompleted = false;
// Processing.
if(!taskCompleted) {
    // Continue processing
}
```

`&&` `||`

Logical AND and OR, which are used to link conditions together.

```
bool myTaskCompleted = false;
int totalCount = 0;
// Processing.
if(!myTaskCompleted && totalCount < 12) {
    // Continue processing.
}
```

Working with File and Folder Paths in Code

You'll often work with file and folder paths in your code. Here is an example of physical folder structure for a website as it might appear on your development computer:

`C:\WebSites\MyWebSite default.cshtml datafile.txt \images Logo.jpg \styles Styles.css`

Here are some essential details about URLs and paths:

- A URL begins with either a domain name (`http://www.example.com`) or a server name (`http://localhost`, `http://mycomputer`).
- A URL corresponds to a physical path on a host computer. For example, `http://myserver` might correspond to the folder *C:\websites\mywebsite* on the server.
- A virtual path is shorthand to represent paths in code without having to specify the full path. It includes the portion of a URL that follows the domain or server name. When you use virtual paths, you can move your code to a different domain or server without having to update the paths.

Here's an example to help you understand the differences:

COMPLETE URL	`HTTP://MYCOMPANYSERVER/HUMANRESOURCES/COMPANYPOLICY.HTM`
Server name	*mycompanyserver*

COMPLETE URL	`HTTP://MYCOMPANYSERVER/HUMANRESOURCES/COMPANYPOLICY.HTM`
Virtual path	*/humanresources/CompanyPolicy.htm*
Physical path	*C:\mywebsites\humanresources\CompanyPolicy.htm*

The virtual root is /, just like the root of your C: drive is . (Virtual folder paths always use forward slashes.) The virtual path of a folder doesn't have to have the same name as the physical folder; it can be an alias. (On production servers, the virtual path rarely matches an exact physical path.)

When you work with files and folders in code, sometimes you need to reference the physical path and sometimes a virtual path, depending on what objects you're working with. ASP.NET gives you these tools for working with file and folder paths in code: the `Server.MapPath` method, and the `~` operator and `Href` method.

Converting virtual to physical paths: the Server.MapPath method

The `Server.MapPath` method converts a virtual path (like */default.cshtml*) to an absolute physical path (like *C:\WebSites\MyWebSiteFolder\default.cshtml*). You use this method any time you need a complete physical path. A typical example is when you're reading or writing a text file or image file on the web server.

You typically don't know the absolute physical path of your site on a hosting site's server, so this method can convert the path you do know — the virtual path — to the corresponding path on the server for you. You pass the virtual path to a file or folder to the method, and it returns the physical path:

```
@{
    var dataFilePath = "~/dataFile.txt";
}
<!-- Displays a physical path C:\Websites\MyWebSite\datafile.txt  -->
<p>@Server.MapPath(dataFilePath)</p>
```

Referencing the virtual root: the ~ operator and Href method

In a *.cshtml* or *.vbhtml* file, you can reference the virtual root path using the `~` operator. This is very handy because you can move pages around in a site, and any links they contain to other pages won't be broken. It's also handy in case you ever move your website to a different location. Here are some examples:

```
@{
    var myImagesFolder = "~/images";
    var myStyleSheet = "~/styles/StyleSheet.css";
}
```

If the website is `http://myserver/myapp`, here's how ASP.NET will treat these paths when the page runs:

- `myImagesFolder` : `http://myserver/myapp/images`
- `myStyleSheet` : `http://myserver/myapp/styles/Stylesheet.css`

(You won't actually see these paths as the values of the variable, but ASP.NET will treat the paths as if that's what they were.)

You can use the `~` operator both in server code (as above) and in markup, like this:

```
<!-- Examples of using the ~ operator in markup in ASP.NET Web Pages -->

<a href="~/Default">Home</a>
<img src="~/images/MyImages.png" />
```

In markup, you use the `~` operator to create paths to resources like image files, other web pages, and CSS files. When the page runs, ASP.NET looks through the page (both code and markup) and resolves all the `~` references to the appropriate path.

Conditional Logic and Loops

ASP.NET server code lets you perform tasks based on conditions and write code that repeats statements a specific number of times (that is, code that runs a loop).

Testing Conditions

To test a simple condition you use the `if` statement, which returns true or false based on a test you specify:

```
@{
  var showToday = true;
  if(showToday)
  {
    @DateTime.Today;
  }
}
```

The `if` keyword starts a block. The actual test (condition) is in parentheses and returns true or false. The statements that run if the test is true are enclosed in braces. An `if` statement can include an `else` block that specifies statements to run if the condition is false:

```
@{
  var showToday = false;
  if(showToday)
  {
    @DateTime.Today;
  }
  else
  {
    <text>Sorry!</text>
  }
}
```

You can add multiple conditions using an `else if` block:

```
@{
    var theBalance = 4.99;
    if(theBalance == 0)
    {
        <p>You have a zero balance.</p>
    }
    else if (theBalance  > 0 && theBalance <= 5)
    {
        <p>Your balance of $@theBalance is very low.</p>
    }
    else
    {
        <p>Your balance is: $@theBalance</p>
    }
}
```

In this example, if the first condition in the if block is not true, the `else if` condition is checked. If that condition is met, the statements in the `else if` block are executed. If none of the conditions are met, the statements in the `else` block are executed. You can add any number of else if blocks, and then close with an `else` block as the "everything else" condition.

To test a large number of conditions, use a `switch` block:

```
@{
    var weekday = "Wednesday";
    var greeting = "";

    switch(weekday)
    {
        case "Monday":
            greeting = "Ok, it's a marvelous Monday";
            break;
        case "Tuesday":
            greeting = "It's a tremendous Tuesday";
            break;
        case "Wednesday":
            greeting = "Wild Wednesday is here!";
            break;
        default:
            greeting = "It's some other day, oh well.";
            break;
    }

    <p>Since it is @weekday, the message for today is: @greeting</p>
}
```

The value to test is in parentheses (in the example, the `weekday` variable). Each individual test uses a `case` statement that ends with a colon (:). If the value of a `case` statement matches the test value, the code in that case block is executed. You close each case statement with a `break` statement. (If you forget to include break in each `case` block, the code from the next `case` statement will run also.) A `switch` block often has a `default` statement as the last case for an "everything else" option that runs if none of the other cases are true.

The result of the last two conditional blocks displayed in a browser:

Looping Code

You often need to run the same statements repeatedly. You do this by looping. For example, you often run the same statements for each item in a collection of data. If you know exactly how many times you want to loop, you can use a `for` loop. This kind of loop is especially useful for counting up or counting down:

```
@for(var i = 10; i < 21; i++)
{
    <p>Line #: @i</p>
}
```

The loop begins with the `for` keyword, followed by three statements in parentheses, each terminated with a semicolon.

- Inside the parentheses, the first statement (`var i=10;`) creates a counter and initializes it to 10. You don't have to name the counter `i` — you can use any variable. When the `for` loop runs, the counter is automatically incremented.
- The second statement (`i < 21;`) sets the condition for how far you want to count. In this case, you want it to

go to a maximum of 20 (that is, keep going while the counter is less than 21).

- The third statement (`i++`) uses an increment operator, which simply specifies that the counter should have 1 added to it each time the loop runs.

Inside the braces is the code that will run for each iteration of the loop. The markup creates a new paragraph (`<p>` element) each time and adds a line to the output, displaying the value of `i` (the counter). When you run this page, the example creates 11 lines displaying the output, with the text in each line indicating the item number.

If you're working with a collection or array, you often use a `foreach` loop. A collection is a group of similar objects, and the `foreach` loop lets you carry out a task on each item in the collection. This type of loop is convenient for collections, because unlike a `for` loop, you don't have to increment the counter or set a limit. Instead, the `foreach` loop code simply proceeds through the collection until it's finished.

For example, the following code returns the items in the `Request.ServerVariables` collection, which is an object that contains information about your web server. It uses a `foreac` h loop to display the name of each item by creating a new `<li>` element in an HTML bulleted list.

```
<ul>
@foreach (var myItem in Request.ServerVariables)
{
    <li>@myItem</li>
}
</ul>
```

The `foreach` keyword is followed by parentheses where you declare a variable that represents a single item in the collection (in the example, `var item`), followed by the `in` keyword, followed by the collection you want to loop through. In the body of the `foreach` loop, you can access the current item using the variable that you declared earlier.

To create a more general-purpose loop, use the `while` statement:

```
@{
    var countNum = 0;
    while (countNum < 50)
    {
        countNum += 1;
        <p>Line #@countNum: </p>
    }
}
```

A `while` loop begins with the `while` keyword, followed by parentheses where you specify how long the loop continues (here, for as long as `countNum` is less than 50), then the block to repeat. Loops typically increment (add to) or decrement (subtract from) a variable or object used for counting. In the example, the `+=` operator adds 1 to `countNum` each time the loop runs. (To decrement a variable in a loop that counts down, you would use the decrement operator `-=`).

Objects and Collections

Nearly everything in an ASP.NET website is an object, including the web page itself. This section discusses some important objects you'll work with frequently in your code.

Page Objects

The most basic object in ASP.NET is the page. You can access properties of the page object directly without any qualifying object. The following code gets the page's file path, using the `Request` object of the page:

```
@{
    var path = Request.FilePath;
}
```

To make it clear that you're referencing properties and methods on the current page object, you can optionally use the keyword `this` to represent the page object in your code. Here is the previous code example, with `this` added to represent the page:

```
@{
    var path = this.Request.FilePath;
}
```

You can use properties of the `Page` object to get a lot of information, such as:

- `Request`. As you've already seen, this is a collection of information about the current request, including what type of browser made the request, the URL of the page, the user identity, etc.
- `Response`. This is a collection of information about the response (page) that will be sent to the browser when the server code has finished running. For example, you can use this property to write information into the response.

  ```
  @{
      // Access the page's Request object to retrieve the Url.
      var pageUrl = this.Request.Url;
  }
  <a href="@pageUrl">My page</a>
  ```

Collection Objects (Arrays and Dictionaries)

A *collection* is a group of objects of the same type, such as a collection of `Customer` objects from a database. ASP.NET contains many built-in collections, like the `Request.Files` collection.

You'll often work with data in collections. Two common collection types are the *array* and the *dictionary*. An array is useful when you want to store a collection of similar items but don't want to create a separate variable to hold each item:

```
@* Array block 1: Declaring a new array using braces. *@
@{
    <h3>Team Members</h3>
    string[] teamMembers = {"Matt", "Joanne", "Robert", "Nancy"};
    foreach (var person in teamMembers)
    {
        <p>@person</p>
    }
}
```

With arrays, you declare a specific data type, such as `string`, `int`, or `DateTime`. To indicate that the variable can contain an array, you add brackets to the declaration (such as `string[]` or `int[]`). You can access items in an array using their position (index) or by using the `foreach` statement. Array indexes are zero-based — that is, the first item is at position 0, the second item is at position 1, and so on.

```
@{
    string[] teamMembers = {"Matt", "Joanne", "Robert", "Nancy"};
    <p>The number of names in the teamMembers array: @teamMembers.Length </p>
    <p>Robert is now in position: @Array.IndexOf(teamMembers, "Robert")</p>
    <p>The array item at position 2 (zero-based) is @teamMembers[2]</p>
    <h3>Current order of team members in the list</h3>
    foreach (var name in teamMembers)
    {
        <p>@name</p>
    }
    <h3>Reversed order of team members in the list</h3>
    Array.Reverse(teamMembers);
    foreach (var reversedItem in teamMembers)
    {
        <p>@reversedItem</p>
    }
}
```

You can determine the number of items in an array by getting its `Length` property. To get the position of a specific item in the array (to search the array), use the `Array.IndexOf` method. You can also do things like reverse the contents of an array (the `Array.Reverse` method) or sort the contents (the `Array.Sort` method).

The output of the string array code displayed in a browser:

A dictionary is a collection of key/value pairs, where you provide the key (or name) to set or retrieve the corresponding value:

```
@{
    var myScores = new Dictionary<string, int>();
    myScores.Add("test1", 71);
    myScores.Add("test2", 82);
    myScores.Add("test3", 100);
    myScores.Add("test4", 59);
}
<p>My score on test 3 is: @myScores["test3"]%</p>
@{myScores["test4"] = 79;}
<p>My corrected score on test 4 is: @myScores["test4"]%</p>
```

To create a dictionary, you use the `new` keyword to indicate that you're creating a new dictionary object. You can assign a dictionary to a variable using the `var` keyword. You indicate the data types of the items in the dictionary using angle brackets (`< >`). At the end of the declaration, you must add a pair of parentheses, because this is actually a method that creates a new dictionary.

To add items to the dictionary, you can call the `Add` method of the dictionary variable (`myScores` in this case), and then specify a key and a value. Alternatively, you can use square brackets to indicate the key and do a simple assignment, as in the following example:

```
myScores["test4"] = 79;
```

To get a value from the dictionary, you specify the key in brackets:

```
var testScoreThree = myScores["test3"];
```

Calling Methods with Parameters

As you read earlier in this article, the objects that you program with can have methods. For example, a `Database` object might have a `Database.Connect` method. Many methods also have one or more parameters. A *parameter* is a value that you pass to a method to enable the method to complete its task. For example, look at a declaration for the `Request.MapPath` method, which takes three parameters:

```
public string MapPath(string virtualPath, string baseVirtualDir,
    bool allowCrossAppMapping);
```

(The line has been wrapped to make it more readable. Remember that you can put line breaks almost any place except inside strings that are enclosed in quotation marks.)

This method returns the physical path on the server that corresponds to a specified virtual path. The three parameters for the method are `virtualPath`, `baseVirtualDir`, and `allowCrossAppMapping`. (Notice that in the declaration, the parameters are listed with the data types of the data that they'll accept.) When you call this method, you must supply values for all three parameters.

The Razor syntax gives you two options for passing parameters to a method: *positional parameters* and *named parameters*. To call a method using positional parameters, you pass the parameters in a strict order that's specified in the method declaration. (You would typically know this order by reading documentation for the method.) You must follow the order, and you can't skip any of the parameters — if necessary, you pass an empty string (`""`) or `null` for a positional parameter that you don't have a value for.

The following example assumes you have a folder named *scripts* on your website. The code calls the `Request.MapPath` method and passes values for the three parameters in the correct order. It then displays the resulting mapped path.

```
@{
    // Pass parameters to a method using positional parameters.
    var myPathPositional = Request.MapPath("/scripts", "/", true);
}
<p>@myPathPositional</p>
```

When a method has many parameters, you can keep your code more readable by using named parameters. To call a method using named parameters, you specify the parameter name followed by a colon (:), and then the value. The advantage of named parameters is that you can pass them in any order you want. (A disadvantage is that the method call is not as compact.)

The following example calls the same method as above, but uses named parameters to supply the values:

```
@{
    // Pass parameters to a method using named parameters.
    var myPathNamed = Request.MapPath(baseVirtualDir: "/",
        allowCrossAppMapping: true, virtualPath: "/scripts");
}
<p>@myPathNamed</p>
```

As you can see, the parameters are passed in a different order. However, if you run the previous example and this example, they'll return the same value.

Handling Errors

Try-Catch Statements

You'll often have statements in your code that might fail for reasons outside your control. For example:

- If your code tries to create or access a file, all sorts of errors might occur. The file you want might not exist, it might be locked, the code might not have permissions, and so on.
- Similarly, if your code tries to update records in a database, there can be permissions issues, the connection to the database might be dropped, the data to save might be invalid, and so on.

In programming terms, these situations are called *exceptions*. If your code encounters an exception, it generates (throws) an error message that's, at best, annoying to users:

In situations where your code might encounter exceptions, and in order to avoid error messages of this type, you

can use `try/catch` statements. In the `try` statement, you run the code that you're checking. In one or more `catch` statements, you can look for specific errors (specific types of exceptions) that might have occurred. You can include as many `catch` statements as you need to look for errors that you are anticipating.

> **NOTE**
> We recommend that you avoid using the `Response.Redirect` method in `try/catch` statements, because it can cause an exception in your page.

The following example shows a page that creates a text file on the first request and then displays a button that lets the user open the file. The example deliberately uses a bad file name so that it will cause an exception. The code includes `catch` statements for two possible exceptions: `FileNotFoundException`, which occurs if the file name is bad, and `DirectoryNotFoundException`, which occurs if ASP.NET can't even find the folder. (You can uncomment a statement in the example in order to see how it runs when everything works properly.)

If your code didn't handle the exception, you would see an error page like the previous screen shot. However, the `try/catch` section helps prevent the user from seeing these types of errors.

```
@{
    var dataFilePath = "~/dataFile.txt";
    var fileContents = "";
    var physicalPath = Server.MapPath(dataFilePath);
    var userMessage = "Hello world, the time is " + DateTime.Now;
    var userErrMsg = "";
    var errMsg = "";

    if(IsPost)
    {
        // When the user clicks the "Open File" button and posts
        // the page, try to open the created file for reading.
        try {
            // This code fails because of faulty path to the file.
            fileContents = File.ReadAllText(@"c:\batafile.txt");

            // This code works. To eliminate error on page,
            // comment the above line of code and uncomment this one.
            //fileContents = File.ReadAllText(physicalPath);
        }
        catch (FileNotFoundException ex) {
            // You can use the exception object for debugging, logging, etc.
            errMsg = ex.Message;
            // Create a friendly error message for users.
            userErrMsg = "A file could not be opened, please contact "
                + "your system administrator.";
        }
        catch (DirectoryNotFoundException ex) {
            // Similar to previous exception.
            errMsg = ex.Message;
            userErrMsg = "A directory was not found, please contact "
                + "your system administrator.";
        }
    }
    else
    {
        // The first time the page is requested, create the text file.
        File.WriteAllText(physicalPath, userMessage);
    }
}

<!DOCTYPE html>
<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title>Try-Catch Statements</title>
    </head>
    <body>
    <form method="POST" action="" >
      <input type="Submit" name="Submit" value="Open File"/>
    </form>

    <p>@fileContents</p>
    <p>@userErrMsg</p>

Introduction to ASP.NET Web Programming Using the Razor Syntax (Visual Basic)

2/20/2020 • 36 minutes to read • Edit Online

by Tom FitzMacken

This article gives you an overview of programming with ASP.NET Web Pages using the Razor syntax and Visual Basic. ASP.NET is Microsoft's technology for running dynamic web pages on web servers.

What you'll learn:

- The top 8 programming tips for getting started with programming ASP.NET Web Pages using Razor syntax.
- Basic programming concepts you'll need.
- What ASP.NET server code and the Razor syntax is all about.

Software versions

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

Most examples of using ASP.NET Web Pages with Razor syntax use C#. But the Razor syntax also supports Visual Basic. To program an ASP.NET web page in Visual Basic, you create a web page with a *.vbhtml* filename extension, and then add Visual Basic code. This article gives you an overview of working with the Visual Basic language and syntax to create ASP.NET Webpages.

> **NOTE**
>
> The default website templates for Microsoft WebMatrix (**Bakery**, **Photo Gallery**, and **Starter Site**, etc.) are available in C# and Visual Basic versions. You can install the Visual Basic templates by as NuGet packages. Website templates are installed in the root folder of your site in a folder named *Microsoft Templates*.

The Top 8 Programming Tips

This section lists a few tips that you absolutely need to know as you start writing ASP.NET server code using the Razor syntax.

1. You add code to a page using the @ character

The `@` character starts inline expressions, single-statement blocks, and multi-statement blocks:

```
<!-- Single statement blocks  -->
@Code  Dim total = 7  End Code
@Code  Dim myMessage = "Hello World" End Code

<!-- Inline expressions -->
<p>The value of your account is: @total </p>
<p>The value of myMessage is: @myMessage</p>

<!-- Multi-statement block -->
@Code
    Dim greeting = "Welcome to our site!"
    Dim weekDay = DateTime.Now.DayOfWeek
    Dim greetingMessage = greeting & " Today is: " & weekDay.ToString()
End Code
<p>The greeting is: @greetingMessage</p>
```

The result displayed in a browser:

TIP

HTML Encoding

When you display content in a page using the `@` character, as in the preceding examples, ASP.NET HTML-encodes the output. This replaces reserved HTML characters (such as `<` and `>` and `&`) with codes that enable the characters to be displayed as characters in a web page instead of being interpreted as HTML tags or entities. Without HTML encoding, the output from your server code might not display correctly, and could expose a page to security risks.

If your goal is to output HTML markup that renders tags as markup (for example `<p></p>` for a paragraph or `<em></em>` to emphasize text), see the section Combining Text, Markup, and Code in Code Blocks later in this article.

You can read more about HTML encoding in Working with HTML Forms in ASP.NET Web Pages Sites.

2. You enclose code blocks with Code...End Code

A code block includes one or more code statements and is enclosed with the keywords `Code` and `End Code`. Place the opening `Code` keyword immediately after the `@` character — there can't be whitespace between them.

```
<!-- Single statement block.  -->
@Code
    Dim theMonth = DateTime.Now.Month
End Code
<p>The numeric value of the current month: @theMonth</p>

<!-- Multi-statement block. -->
@Code
    Dim outsideTemp = 79
    Dim weatherMessage = "Hello, it is " & outsideTemp & " degrees."
End Code
<p>Today's weather: @weatherMessage</p>
```

The result displayed in a browser:

3. Inside a block, you end each code statement with a line break

In a Visual Basic code block, each statement ends with a line break. (Later in the article you'll see a way to wrap a long code statement into multiple lines if needed.)

```
<!-- Single statement block. -->
@Code
    Dim theMonth = DateTime.Now.Month
End Code

<!-- Multi-statement block. -->
@Code
    Dim outsideTemp = 79
    Dim weatherMessage = "Hello, it is " & outsideTemp & " degrees."
End Code

<!-- An inline expression, so no line break needed. -->
<p>Today's weather: @weatherMessage</p>
```

4. You use variables to store values

You can store values in a *variable*, including strings, numbers, and dates, etc. You create a new variable using the `Dim` keyword. You can insert variable values directly in a page using `@`.

```
<!-- Storing a string -->
@Code
    Dim welcomeMessage = "Welcome, new members!"
End Code
<p>@welcomeMessage</p>

<!-- Storing a date -->
@Code
    Dim year = DateTime.Now.Year
End Code

<!-- Displaying a variable -->
<p>Welcome to our new members who joined in @year!</p>
```

The result displayed in a browser:

5. You enclose literal string values in double quotation marks

A *string* is a sequence of characters that are treated as text. To specify a string, you enclose it in double quotation marks:

```
@Code
    Dim myString = "This is a string literal"
End Code
```

To embed double quotation marks within a string value, insert two double quotation mark characters. If you want the double quotation character to appear once in the page output, enter it as `""` within the quoted string, and if you want it to appear twice, enter it as `""""` within the quoted string.

```
<!-- Embedding double quotation marks in a string -->
@Code
    Dim myQuote = "The person said: ""Hello, today is Monday."""
End Code
<p>@myQuote</p>
```

The result displayed in a browser:

6. Visual Basic code is not case sensitive

The Visual Basic language is not case sensitive. Programming keywords (like `Dim`, `If`, and `True`) and variable names (like `myString`, or `subTotal`) can be written in any case.

The following lines of code assign a value to the variable `lastname` using a lowercase name, and then output the variable value to the page using an uppercase name.

```
@Code
    Dim lastName = "Smith"
    ' Keywords like dim are also not case sensitive.
    DIM someNumber = 7
End Code
<p>The value of the <code>lastName</code> variable is: @LASTNAME</p>
```

The result displayed in a browser:

7. Much of your coding involves working with objects

An object represents a thing that you can program with — a page, a text box, a file, an image, a web request, an email message, a customer record (database row), etc. Objects have properties that describe their characteristics — a text box object has a `Text` property, a request object has a `Url` property, an email message has a `From` property, and a customer object has a `FirstName` property. Objects also have methods that are the "verbs" they

can perform. Examples include a file object's `Save` method, an image object's `Rotate` method, and an email object's `Send` method.

You'll often work with the `Request` object, which gives you information like the values of form fields on the page (text boxes, etc.), what type of browser made the request, the URL of the page, the user identity, etc. This example shows how to access properties of the `Request` object and how to call the `MapPath` method of the `Request` object, which gives you the absolute path of the page on the server:

```
<table border="1">
    <tr>
        <td>Requested URL</td>
        <td>Relative Path</td>
        <td>Full Path</td>
        <td>HTTP Request Type</td>
    </tr>
    <tr>
        <td>@Request.Url</td>
        <td>@Request.FilePath</td>
        <td>@Request.MapPath(Request.FilePath)</td>
        <td>@Request.RequestType</td>
    </tr>
</table>
```

The result displayed in a browser:

8. You can write code that makes decisions

A key feature of dynamic web pages is that you can determine what to do based on conditions. The most common way to do this is with the `If` statement (and optional `Else` statement).

```
@Code
   Dim result = ""
   If IsPost Then
      result = "This page was posted using the Submit button."
   Else
      result = "This was the first request for this page."
   End If
End Code
<!DOCTYPE html>
<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title>Write Code that Makes Decisions</title>
    </head>
<body>

    <form method="POST" action="" >
        <input type="Submit" name="Submit" value="Submit"/>
        <p>@result</p>
    </form>

</body>
</html>
```

The statement `If IsPost` is a shorthand way of writing `If IsPost = True`. Along with `If` statements, there are a variety of ways to test conditions, repeat blocks of code, and so on, which are described later in this article.

The result displayed in a browser (after clicking **Submit**):

TIP

HTTP GET and POST Methods and the IsPost Property

The protocol used for web pages (HTTP) supports a very limited number of methods ("verbs") that are used to make requests to the server. The two most common ones are GET, which is used to read a page, and POST, which is used to submit a page. In general, the first time a user requests a page, the page is requested using GET. If the user fills in a form and then clicks **Submit**, the browser makes a POST request to the server.

In web programming, it's often useful to know whether a page is being requested as a GET or as a POST so that you know how to process the page. In ASP.NET Web Pages, you can use the `IsPost` property to see whether a request is a GET or a POST. If the request is a POST, the `IsPost` property will return true, and you can do things like read the values of text boxes on a form. Many examples you'll see show you how to process the page differently depending on the value of `IsPost`.

A Simple Code Example

This procedure shows you how to create a page that illustrates basic programming techniques. In the example, you create a page that lets users enter two numbers, then it adds them and displays the result.

1. In your editor, create a new file and name it *AddNumbers.vbhtml*.

2. Copy the following code and markup into the page, replacing anything already in the page.

```
@Code
    Dim total = 0
    Dim totalMessage = ""
    if IsPost Then
        ' Retrieve the numbers that the user entered.
        Dim num1 = Request("text1")
        Dim num2 = Request("text2")
        ' Convert the entered strings into integers numbers and add.
        total = num1.AsInt() + num2.AsInt()
        totalMessage = "Total = " & total
    End If
End Code
<!DOCTYPE html>
<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title>Adding Numbers</title>
        <style type="text/css">
            body {background-color: beige; font-family: Verdana, Ariel;
                margin: 50px;
                }
            form {padding: 10px; border-style: solid; width: 250px;}
        </style>
    </head>
<body>
    <p>Enter two whole numbers and click <strong>Add</strong> to display the result.</p>
    <p></p>
    <form action="" method="post">
    <p><label for="text1">First Number:</label>
    <input type="text" name="text1" />
    </p>
    <p><label for="text2">Second Number:</label>
    <input type="text" name="text2" />
    </p>
    <p><input type="submit" value="Add" /></p>
    </form>
    <p>@totalMessage</p>
</body>
</html>
```

Here are some things for you to note:

- The `@` character starts the first block of code in the page, and it precedes the `totalMessage` variable embedded near the bottom.
- The block at the top of the page is enclosed in `Code...End Code`.
- The variables `total`, `num1`, `num2`, and `totalMessage` store several numbers and a string.
- The literal string value assigned to the `totalMessage` variable is in double quotation marks.
- Because Visual Basic code is not case sensitive, when the `totalMessage` variable is used near the bottom of the page, its name only needs to match the spelling of the variable declaration at the top of the page. The casing doesn't matter.
- The expression `num1.AsInt()` + `num2.AsInt()` shows how to work with objects and methods. The `AsInt` method on each variable converts the string entered by a user to a whole number (an integer) that can be added.
- The `<form>` tag includes a `method="post"` attribute. This specifies that when the user clicks **Add**, the page will be sent to the server using the HTTP POST method. When the page is submitted, the code `If IsPost` evaluates to true and the conditional code runs, displaying the result of adding the numbers.

3. Save the page and run it in a browser. (Make sure the page is selected in the **Files** workspace before you run it.) Enter two whole numbers and then click the **Add** button.

Visual Basic Language and Syntax

Earlier you saw a basic example of how to create an ASP.NET web page, and how you can add server code to HTML markup. Here you'll learn the basics of using Visual Basic to write ASP.NET server code using the Razor syntax — that is, the programming language rules.

If you're experienced with programming (especially if you've used C, C++, C#, Visual Basic, or JavaScript), much of what you read here will be familiar. You'll probably need to familiarize yourself only with how WebMatrix code is added to markup in *.vbhtml* files.

Combining text, markup, and code in code blocks

In server code blocks, you'll often want to output text and markup to the page. If a server code block contains text that's not code and that instead should be rendered as is, ASP.NET needs to be able to distinguish that text from code. There are several ways to do this.

- Enclose the text in an HTML block element like `<p></p>` or `<em></em>`:

  ```
  @If IsPost Then
      ' This line has all content between matched <p> tags.
      @<p>Hello, the time is @DateTime.Now and this page is a postback!</p>
  Else
      ' All content between matched tags, followed by server code.
      @<p>Hello, <em>Stranger!</em> today is: </p> @DateTime.Now
  End If
  ```

  The HTML element can include text, additional HTML elements, and server-code expressions. When ASP.NET sees the opening HTML tag (for example, `<p>`), it renders everything the element and its content as is to the browser (and resolves the server-code expressions).

- Use the `@:` operator or the `<text>` element. The `@:` outputs a single line of content containing plain text or unmatched HTML tags; the `<text>` element encloses multiple lines to output. These options are useful when you don't want to render an HTML element as part of the output.

```
@If IsPost Then
    ' Plain text followed by an unmatched HTML tag and server code.
    @:The time is: <br /> @DateTime.Now
    ' Server code and then plain text, matched tags, and more text.
    @DateTime.Now @:is the <em>current</em> time.
End If
```

The following example repeats the previous example but uses a single pair of `<text>` tags to enclose the text to render.

```
@If IsPost Then
    @<text>
    The time is: <br /> @DateTime.Now
    @DateTime.Now is the <em>current</em> time.
    </text>
End If
```

In the following example, the `<text>` and `</text>` tags enclose three lines, all of which have some uncontained text and unmatched HTML tags (`<br />`), along with server code and matched HTML tags. Again, you could also precede each line individually with the `@:` operator; either way works.

```
@Code
    dim minTemp = 75
    @<text>It is the month of @DateTime.Now.ToString("MMMM"), and
    it's a <em>great</em> day! <p>You can go swimming if it's at
    least @minTemp degrees.</p></text>
End Code
```

> **NOTE**
>
> When you output text as shown in this section — using an HTML element, the `@:` operator, or the `<text>` element — ASP.NET doesn't HTML-encode the output. (As noted earlier, ASP.NET does encode the output of server code expressions and server code blocks that are preceded by `@`, except in the special cases noted in this section.)

Whitespace

Extra spaces in a statement (and outside of a string literal) don't affect the statement:

```
@Code Dim personName =    "Smith"    End Code
```

Breaking long statements into multiple lines

You can break a long code statement into multiple lines by using the underscore character `_` (which in Visual Basic is called the *continuation character*) after each line of code. To break a statement onto the next line, at the end of the line add a space and then the continuation character. Continue the statement on the next line. You can wrap statements onto as many lines as you need to improve readability. The following statements are the same:

```
@Code
    Dim familyName _
    =  "Smith"
End Code

@Code
    Dim _
    theName _
    = _
    "Smith"
End Code
```

However, you can't wrap a line in the middle of a string literal. The following example doesn't work:

```
@Code
    ' Doesn't work.
    Dim test = "This is a long _
      string"
End Code
```

To combine a long string that wraps to multiple lines like the above code, you would need to use the *concatenation operator* (`&`), which you'll see later in this article.

Code comments

Comments let you leave notes for yourself or others. Razor syntax comments are prefixed with `@*` and end with `*@`.

```
@* A single-line comment is added like this example. *@

@*
    This is a multiline code comment.
    It can continue for any number of lines.
*@
```

Within code blocks you can use the Razor syntax comments, or you can use ordinary Visual Basic comment character, which is a single quote (`'`) prefixed to each line.

```
@Code
    ' You can make comments in blocks by just using ' before each line.
End Code

@Code
    ' There is no multi-line comment character in Visual Basic.
    ' You use a ' before each line you want to comment.
End Code
```

Variables

A variable is a named object that you use to store data. You can name variables anything, but the name must begin with an alphabetic character and it cannot contain whitespace or reserved characters. In Visual Basic, as you saw earlier, the case of the letters in a variable name doesn't matter.

Variables and data types

A variable can have a specific data type, which indicates what kind of data is stored in the variable. You can have string variables that store string values (like "Hello world"), integer variables that store whole-number values (like 3 or 79), and date variables that store date values in a variety of formats (like 4/12/2012 or March 2009). And

there are many other data types you can use.

However, you don't have to specify a type for a variable. In most cases ASP.NET can figure out the type based on how the data in the variable is being used. (Occasionally you must specify a type; you'll see examples where this is true.)

To declare a variable without specifying a type, use `Dim` plus the variable name (for instance, `Dim myVar`). To declare a variable with a type, use `Dim` plus the variable name, followed by `As` and then the type name (for instance, `Dim myVar As String`).

```
@Code
    ' Assigning a string to a variable.
    Dim greeting = "Welcome"

    ' Assigning a number to a variable.
    Dim theCount = 3

    ' Assigning an expression to a variable.
    Dim monthlyTotal = theCount + 5

    ' Assigning a date value to a variable.
    Dim today = DateTime.Today

    ' Assigning the current page's URL to a variable.
    Dim myPath = Request.Url

    ' Declaring variables using explicit data types.
    Dim name as String = "Joe"
    Dim count as Integer = 5
    Dim tomorrow as DateTime = DateTime.Now.AddDays(1)
End Code
```

The following example shows some inline expressions that use the variables in a web page.

```
@Code
    ' Embedding the value of a variable into HTML markup.
    ' Precede the markup with @ because we are in a code block.
    @<p>@greeting, friends!</p>
End Code

<!-- Using a variable with an inline expression in HTML. -->
<p>The predicted annual total is: @( monthlyTotal * 12)</p>

<!--  Displaying the page URL with a variable. -->
<p>The URL to this page is:  @myPath</p>
```

The result displayed in a browser:

Converting and testing data types

Although ASP.NET can usually determine a data type automatically, sometimes it can't. Therefore, you might need to help ASP.NET out by performing an explicit conversion. Even if you don't have to convert types, sometimes it's helpful to test to see what type of data you might be working with.

The most common case is that you have to convert a string to another type, such as to an integer or date. The following example shows a typical case where you must convert a string to a number.

```
@Code
    Dim total = 0
    Dim totalMessage = ""
    if IsPost Then
        ' Retrieve the numbers that the user entered.
        Dim num1 = Request("text1")
        Dim num2 = Request("text2")
        ' Convert the entered strings into integers numbers and add.
        total = num1.AsInt() + num2.AsInt()
        totalMessage = "Total = " & total
    End If
End Code
```

As a rule, user input comes to you as strings. Even if you've prompted the user to enter a number, and even if they've entered a digit, when user input is submitted and you read it in code, the data is in string format. Therefore, you must convert the string to a number. In the example, if you try to perform arithmetic on the values without converting them, the following error results, because ASP.NET cannot add two strings:

`Cannot implicitly convert type 'string' to 'int'.`

To convert the values to integers, you call the `AsInt` method. If the conversion is successful, you can then add the numbers.

The following table lists some common conversion and test methods for variables.

Method	Description	Example

`AsInt(), IsInt()`	Converts a string that represents a whole number (like "593") to an integer.	`Dim myIntNumber = 0`
		`Dim myStringNum = "539"`
		`If myStringNum.IsInt() Then`
		`  myIntNumber = myStringNum.AsInt()`
		`End If`

`AsBool(), IsBool()`	Converts a string like "true" or "false" to a Boolean type.	`Dim myStringBool = "True"` `Dim myVar = myStringBool.AsBool()`
`AsFloat(), IsFloat()`	Converts a string that has a decimal value like "1.3" or "7.439" to a floating-point number.	`Dim myStringFloat = "41.432895"` `Dim myFloatNum = myStringFloat.AsFloat()`

`AsDecimal(), IsDecimal()`

Converts a string that has a decimal value like "1.3" or "7.439" to a decimal number. (In ASP.NET, a decimal number is more precise than a floating-point number.)

```
Dim myStringDec = "10317.425"
Dim myDecNum = myStringDec.AsDecimal()
```

`AsDateTime(), IsDateTime()`

Converts a string that represents a date and time value to the ASP.NET `DateTime` type.

```
Dim myDateString = "12/27/2012"
Dim newDate = myDateString.AsDateTime()
```

`ToString()`

Converts any other data type to a string.

```
Dim num1 As Integer = 17
Dim num2 As Integer = 76

' myString is set to 1776
Dim myString as String = num1.ToString() & _
    num2.ToString()
```

Operators

An operator is a keyword or character that tells ASP.NET what kind of command to perform in an expression. Visual Basic supports many operators, but you only need to recognize a few to get started developing ASP.NET web pages. The following table summarizes the most common operators.

Operator

Description

Examples

`+ - * /`

Math operators used in numerical expressions.

```
@(5 + 13)

Dim netWorth = 150000
Dim newTotal = netWorth * 2
@(newTotal / 2)
```

`=`

Assignment and equality. Depending on context, either assigns the value on the right side of a statement to the object on the left side, or checks the values for equality.

```
Dim age = 17

Dim income = Request("AnnualIncome")
```

`<>`

Inequality. Returns `True` if the values are not equal.

```
Dim theNum = 13
If theNum <> 15 Then
    ' Do something.
End If
```

`< > <= >=`

Less than, greater than, less than or equal, and greater than or equal.

```
If 2 < 3 Then
    ' Do something.
End If

Dim currentCount = 12
If currentCount >= 12 Then
    ' Do something.
End If
```

`&`

Concatenation, which is used to join strings.

```
' The displayed result is "abcdef".
@("abc" & "def")
```

`+= -=`

The increment and decrement operators, which add and subtract 1 (respectively) from a variable.

```
Dim theCount As Integer = 0
theCount += 1 ' Adds 1 to count
```

`.`

Dot. Used to distinguish objects and their properties and methods.

```
Dim myUrl = Request.Url
Dim count = Request("Count").AsInt()
```

`()`

Parentheses. Used to group expressions, to pass parameters to methods, and to access members of arrays and collections.

```
@(3 + 7)

@Request.MapPath(Request.FilePath)
```

`Not`

Not. Reverses a true value to false and vice versa. Typically used as a shorthand way to test for `False` (that is, for not `True`).

```
Dim taskCompleted As Boolean = False
' Processing.
If Not taskCompleted Then
    ' Continue processing
End If
```

`AndAlso OrElse`

Logical AND and OR, which are used to link conditions together.

```
Dim myTaskCompleted As Boolean = false
Dim totalCount As Integer = 0
' Processing.
If (Not myTaskCompleted) AndAlso _
         totalCount < 12 Then
    ' Continue processing.
End If
```

Working with File and Folder Paths in Code

You'll often work with file and folder paths in your code. Here is an example of physical folder structure for a website as it might appear on your development computer:

`C:\WebSites\MyWebSite default.cshtml datafile.txt \images Logo.jpg \styles Styles.css`

Here are some essential details about URLs and paths:

- A URL begins with either a domain name (`http://www.example.com`) or a server name (`http://localhost`, `http://mycomputer`).
- A URL corresponds to a physical path on a host computer. For example, `http://myserver` might correspond to the folder *C:\websites\mywebsite* on the server.
- A virtual path is shorthand to represent paths in code without having to specify the full path. It includes the portion of a URL that follows the domain or server name. When you use virtual paths, you can move your code to a different domain or server without having to update the paths.

Here's an example to help you understand the differences:

COMPLETE URL	`HTTP://MYCOMPANYSERVER/HUMANRESOURCES/COMPANYPOLICY.HTM`
Server name	*mycompanyserver*
Virtual path	*/humanresources/CompanyPolicy.htm*
Physical path	*C:\mywebsites\humanresources\CompanyPolicy.htm*

The virtual root is /, just like the root of your C: drive is . (Virtual folder paths always use forward slashes.) The virtual path of a folder doesn't have to have the same name as the physical folder; it can be an alias. (On production servers, the virtual path rarely matches an exact physical path.)

When you work with files and folders in code, sometimes you need to reference the physical path and sometimes a virtual path, depending on what objects you're working with. ASP.NET gives you these tools for working with file and folder paths in code: the `Server.MapPath` method, and the `~` operator and `Href` method.

Converting virtual to physical paths: the Server.MapPath method

The `Server.MapPath` method converts a virtual path (like */default.cshtml*) to an absolute physical path (like *C:\WebSites\MyWebSiteFolder\default.cshtml*). You use this method any time you need a complete physical path. A typical example is when you're reading or writing a text file or image file on the web server.

You typically don't know the absolute physical path of your site on a hosting site's server, so this method can convert the path you do know — the virtual path — to the corresponding path on the server for you. You pass the virtual path to a file or folder to the method, and it returns the physical path:

```
@Code
    Dim dataFilePath = "~/dataFile.txt"
End Code

<!-- Displays a physical path C:\Websites\MyWebSite\datafile.txt  -->
<p>@Server.MapPath(dataFilePath)</p>
```

Referencing the virtual root: the ~ operator and Href method

In a *.cshtml* or *.vbhtml* file, you can reference the virtual root path using the `~` operator. This is very handy because you can move pages around in a site, and any links they contain to other pages won't be broken. It's also handy in case you ever move your website to a different location. Here are some examples:

```
@Code
    Dim myImagesFolder = "~/images"
    Dim myStyleSheet = "~/styles/StyleSheet.css"
End Code
```

If the website is `http://myserver/myapp`, here's how ASP.NET will treat these paths when the page runs:

- `myImagesFolder` : `http://myserver/myapp/images`
- `myStyleSheet` : `http://myserver/myapp/styles/Stylesheet.css`

(You won't actually see these paths as the values of the variable, but ASP.NET will treat the paths as if that's what they were.)

You can use the `~` operator both in server code (as above) and in markup, like this:

```
<!-- Examples of using the ~ operator in markup in ASP.NET Web Pages -->

<a href="~/Default">Home</a>
<img src="~/images/MyImages.png" />
```

In markup, you use the `~` operator to create paths to resources like image files, other web pages, and CSS files. When the page runs, ASP.NET looks through the page (both code and markup) and resolves all the `~` references to the appropriate path.

Conditional Logic and Loops

ASP.NET server code lets you perform tasks based on conditions and write code that repeats statements a specific number of times that is, code that runs a loop).

Testing conditions

To test a simple condition you use the `If...Then` statement, which returns `True` or `False` based on a test you specify:

```
@Code
    Dim showToday = True
    If showToday Then
        DateTime.Today
    End If
End Code
```

The `If` keyword starts a block. The actual test (condition) follows the `If` keyword and returns true or false. The `If` statement ends with `Then`. The statements that will run if the test is true are enclosed by `If` and `End If`. An `If` statement can include an `Else` block that specifies statements to run if the condition is false:

```
@Code
    Dim showToday = False
    If showToday Then
        DateTime.Today
    Else
        @<text>Sorry!</text>
    End If
End Code
```

If an `If` statement starts a code block, you don't have to use the normal `Code...End Code` statements to include the blocks. You can just add `@` to the block, and it will work. This approach works with `If` as well as other Visual Basic programming keywords that are followed by code blocks, including `For`, `For Each`, `Do While`, etc.

```
@If showToday Then
    DateTime.Today
Else
    @<text>Sorry!</text>
End If
```

You can add multiple conditions using one or more `ElseIf` blocks:

```
@Code
    Dim theBalance = 4.99
    If theBalance = 0 Then
        @<p>You have a zero balance.</p>
    ElseIf theBalance > 0 AndAlso theBalance <= 5 Then
        ' If the balance is above 0 but less than
        ' or equal to $5, display this message.
        @<p>Your balance of $@theBalance is very low.</p>
    Else
        ' For balances greater than $5, display balance.
        @<p>Your balance is: $@theBalance</p>
    End If
End Code
```

In this example, if the first condition in the `If` block is not true, the `ElseIf` condition is checked. If that condition is met, the statements in the `ElseIf` block are executed. If none of the conditions are met, the statements in the `Else` block are executed. You can add any number of `ElseIf` blocks, and then close with an `Else` block as the "everything else" condition.

To test a large number of conditions, use a `Select Case` block:

```
@Code
    Dim weekday = "Wednesday"
    Dim greeting = ""

    Select Case weekday
        Case "Monday"
            greeting = "Ok, it's a marvelous Monday."
        Case "Tuesday"
            greeting = "It's a tremendous Tuesday."
        Case "Wednesday"
            greeting = "Wild Wednesday is here!"
        Case Else
            greeting = "It's some other day, oh well."
    End Select
End Code
<p>Since it is @weekday, the message for today is: @greeting</p>
```

The value to test is in parentheses (in the example, the weekday variable). Each individual test uses a `Case` statement that lists a value. If the value of a `Case` statement matches the test value, the code in that `Case` block is executed.

The result of the last two conditional blocks displayed in a browser:

Looping code

You often need to run the same statements repeatedly. You do this by looping. For example, you often run the same statements for each item in a collection of data. If you know exactly how many times you want to loop, you can use a `For` loop. This kind of loop is especially useful for counting up or counting down:

```
@For i = 10 To 20
    @<p>Item #: @i</p>
Next i
```

The loop begins with the `For` keyword, followed by three elements:

- Immediately after the `For` statement, you declare a counter variable (you don't have to use `Dim`) and then indicate the range, as in `i = 10 to 20`. This means the variable `i` will start counting at 10 and continue until it reaches 20 (inclusive).
- Between the `For` and `Next` statements is the content of the block. This can contain one or more code statements that execute with each loop.
- The `Next i` statement ends the loop. It increments the counter and starts the next iteration of the loop.

The line of code between the `For` and `Next` lines contains the code that runs for each iteration of the loop. The markup creates a new paragraph (`<p>` element) each time and adds a line to the output, displaying the value of i (the counter). When you run this page, the example creates 11 lines displaying the output, with the text in each line indicating the item number.

If you're working with a collection or array, you often use a `For Each` loop. A collection is a group of similar objects, and the `For Each` loop lets you carry out a task on each item in the collection. This type of loop is convenient for collections, because unlike a `For` loop, you don't have to increment the counter or set a limit. Instead, the `For Each` loop code simply proceeds through the collection until it's finished.

This example returns the items in the `Request.ServerVariables` collection (which contains information about your web server). It uses a `For Each` loop to display the name of each item by creating a new `<li>` element in an HTML bulleted list.

```
<ul>
@For Each myItem In Request.ServerVariables
    @<li>@myItem</li>
Next myItem
</ul>
```

The `For Each` keyword is followed by a variable that represents a single item in the collection (in the example, `myItem`), followed by the `In` keyword, followed by the collection you want to loop through. In the body of the `For Each` loop, you can access the current item using the variable that you declared earlier.

To create a more general-purpose loop, use the `Do While` statement:

```
@Code
    Dim countNum = 0
    Do While countNum < 50
        countNum += 1
        @<p>Line #@countNum: </p>
    Loop
End Code
```

This loop begins with the `Do While` keyword, followed by a condition, followed by the block to repeat. Loops typically increment (add to) or decrement (subtract from) a variable or object used for counting. In the example, the `+=` operator adds 1 to the value of a variable each time the loop runs. (To decrement a variable in a loop that counts down, you would use the decrement operator `-=`.)

Objects and Collections

Nearly everything in an ASP.NET website is an object, including the web page itself. This section discusses some important objects you'll work with frequently in your code.

Page objects

The most basic object in ASP.NET is the page. You can access properties of the page object directly without any qualifying object. The following code gets the page's file path, using the `Request` object of the page:

```
@Code
    Dim path = Request.FilePath
End Code
```

You can use properties of the `Page` object to get a lot of information, such as:

- `Request`. As you've already seen, this is a collection of information about the current request, including what type of browser made the request, the URL of the page, the user identity, etc.
- `Response`. This is a collection of information about the response (page) that will be sent to the browser when the server code has finished running. For example, you can use this property to write information into the response.

```
@Code
    ' Access the page's Request object to retrieve the URL.
    Dim pageUrl = Request.Url
End Code
    <a href="@pageUrl">My page</a>
```

Collection objects (arrays and dictionaries)

A collection is a group of objects of the same type, such as a collection of `Customer` objects from a database. ASP.NET contains many built-in collections, like the `Request.Files` collection.

You'll often work with data in collections. Two common collection types are the *array* and the *dictionary*. An array is useful when you want to store a collection of similar items but don't want to create a separate variable to hold each item:

```
<h3>Team Members</h3>
@Code
    Dim teamMembers() As String = {"Matt", "Joanne", "Robert", "Nancy"}
    For Each name In teamMembers
        @<p>@name</p>
    Next name
End Code
```

With arrays, you declare a specific data type, such as `String`, `Integer`, or `DateTime`. To indicate that the variable can contain an array, you add parentheses to the variable name in the declaration (such as `Dim myVar() As String`). You can access items in an array using their position (index) or by using the `For Each` statement. Array indexes are zero-based — that is, the first item is at position 0, the second item is at position 1, and so on.

```
@Code
    Dim teamMembers() As String = {"Matt", "Joanne", "Robert", "Nancy"}
    @<p>The number of names in the teamMembers array: @teamMembers.Length </p>
    @<p>Robert is now in position: @Array.IndexOf(teamMembers, "Robert")</p>
    @<p>The array item at position 2 (zero-based) is @teamMembers(2)</p>
    @<h3>Current order of team members in the list</h3>
    For Each name In teamMembers
        @<p>@name</p>
    Next name
    @<h3>Reversed order of team members in the list</h3>
    Array.Reverse(teamMembers)
    For Each reversedItem In teamMembers
        @<p>@reversedItem</p>
    Next reversedItem
End Code
```

You can determine the number of items in an array by getting its `Length` property. To get the position of a specific item in the array (that is, to search the array), use the `Array.IndexOf` method. You can also do things like reverse the contents of an array (the `Array.Reverse` method) or sort the contents (the `Array.Sort` method).

The output of the string array code displayed in a browser:

A dictionary is a collection of key/value pairs, where you provide the key (or name) to set or retrieve the corresponding value:

```
@Code
    Dim myScores = New Dictionary(Of String, Integer)()
    myScores.Add("test1", 71)
    myScores.Add("test2", 82)
    myScores.Add("test3", 100)
    myScores.Add("test4", 59)
End Code
<p>My score on test 3 is: @myScores("test3")%</p>
@Code
    myScores("test4") = 79
End Code
<p>My corrected score on test 4 is: @myScores("test4")%</p>
```

To create a dictionary, you use the `New` keyword to indicate that you're creating a new `Dictionary` object. You can assign a dictionary to a variable using the `Dim` keyword. You indicate the data types of the items in the dictionary using parentheses (`( )`). At the end of the declaration, you must add another pair of parentheses, because this is actually a method that creates a new dictionary.

To add items to the dictionary, you can call the `Add` method of the dictionary variable (`myScores` in this case), and then specify a key and a value. Alternatively, you can use parentheses to indicate the key and do a simple assignment, as in the following example:

```
@Code
    myScores("test4") = 79
End Code
```

To get a value from the dictionary, you specify the key in parentheses:

```
@myScores("test4")
```

Calling Methods with Parameters

As you saw earlier in this article, the objects that you program with have methods. For example, a `Database` object might have a `Database.Connect` method. Many methods also have one or more parameters. A *parameter* is a value that you pass to a method to enable the method to complete its task. For example, look at a declaration for the `Request.MapPath` method, which takes three parameters:

```
Public Overridable Function MapPath (virtualPath As String, _
    baseVirtualDir As String, _
    allowCrossAppMapping As Boolean)
```

This method returns the physical path on the server that corresponds to a specified virtual path. The three parameters for the method are `virtualPath`, `baseVirtualDir`, and `allowCrossAppMapping`. (Notice that in the declaration, the parameters are listed with the data types of the data that they'll accept.) When you call this method, you must supply values for all three parameters.

When you're using Visual Basic with the Razor syntax, you have two options for passing parameters to a method: *positional parameters* or *named parameters*. To call a method using positional parameters, you pass the parameters in a strict order that's specified in the method declaration. (You would typically know this order by reading documentation for the method.) You must follow the order, and you can't skip any of the parameters — if necessary, you pass an empty string (`""`) or null for a positional parameter that you don't have a value for.

The following example assumes you have a folder named *scripts* on your website. The code calls the `Request.MapPath` method and passes values for the three parameters in the correct order. It then displays the resulting mapped path.

```
@Code
    ' Pass parameters to a method using positional parameters.
    Dim myPathPositional = Request.MapPath("/scripts", "/", true)
End Code
<p>@myPathPositional</p>
```

When there are many parameters for a method, you can keep your code cleaner and more readable by using named parameters. To call a method using named parameters, specify the parameter name followed by `:=` and then provide the value. An advantage of named parameters is that you can add them in any order you want. (A disadvantage is that the method call is not as compact.)

The following example calls the same method as above, but uses named parameters to supply the values:

```
@Code
    ' Pass parameters to a method using named parameters.
    Dim myPathNamed = Request.MapPath(baseVirtualDir:= "/", allowCrossAppMapping:= true, virtualPath:=
"/scripts")
End Code
<p>@myPathNamed</p>
```

As you can see, the parameters are passed in a different order. However, if you run the previous example and this example, they'll return the same value.

Handling Errors

Try-Catch statements

You'll often have statements in your code that might fail for reasons outside your control. For example:

- If your code tries to open, create, read, or write a file, all sorts of errors might occur. The file you want might not

exist, it might be locked, the code might not have permissions, and so on.

- Similarly, if your code tries to update records in a database, there can be permissions issues, the connection to the database might be dropped, the data to save might be invalid, and so on.

In programming terms, these situations are called *exceptions*. If your code encounters an exception, it generates (throws) an error message that is, at best, annoying to users.

In situations where your code might encounter exceptions, and in order to avoid error messages of this type, you can use `Try/Catch` statements. In the `Try` statement, you run the code that you're checking. In one or more `Catch` statements, you can look for specific errors (specific types of exceptions) that might have occurred. You can include as many `Catch` statements as you need to look for errors that you're anticipating.

> **NOTE**
>
> We recommend that you avoid using the `Response.Redirect` method in `Try/Catch` statements, because it can cause an exception in your page.

The following example shows a page that creates a text file on the first request and then displays a button that lets the user open the file. The example deliberately uses a bad file name so that it will cause an exception. The code includes `Catch` statements for two possible exceptions: `FileNotFoundException`, which occurs if the file name is bad, and `DirectoryNotFoundException`, which occurs if ASP.NET can't even find the folder. (You can uncomment a statement in the example in order to see how it runs when everything works properly.)

If your code didn't handle the exception, you would see an error page like the previous screen shot. However, the `Try/Catch` section helps prevent the user from seeing these types of errors.

```
@Code
    Dim dataFilePath = "~/dataFile.txt"
    Dim fileContents = ""
    Dim physicalPath = Server.MapPath(dataFilePath)
    Dim userMessage = "Hello world, the time is " + DateTime.Now
    Dim userErrMsg = ""
    Dim errMsg = ""

    If IsPost Then
        ' When the user clicks the "Open File" button and posts
        ' the page, try to open the file.
        Try
            ' This code fails because of faulty path to the file.
            fileContents = File.ReadAllText("c:\batafile.txt")

            ' This code works. To eliminate error on page,
            ' comment the above line of code and uncomment this one.
            ' fileContents = File.ReadAllText(physicalPath)

        Catch ex As FileNotFoundException
            ' You can use the exception object for debugging, logging, etc.
            errMsg = ex.Message
            ' Create a friendly error message for users.
            userErrMsg = "The file could not be opened, please contact " _
                & "your system administrator."

        Catch ex As DirectoryNotFoundException
            ' Similar to previous exception.
            errMsg = ex.Message
            userErrMsg = "The file could not be opened, please contact " _
                & "your system administrator."
        End Try
    Else
        ' The first time the page is requested, create the text file.
        File.WriteAllText(physicalPath, userMessage)
    End If
End Code
<!DOCTYPE html>
<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title>Try-Catch Statements</title>
    </head>
    <body>
    <form method="POST" action="" >
      <input type="Submit" name="Submit" value="Open File"/>
    </form>

    <p>@fileContents</p>
    <p>@userErrMsg</p>

    </body>
</html>
```

ASP.NET Web Pages (Razor) FAQ

4/10/2020 • 5 minutes to read • Edit Online

by Tom FitzMacken

> **NOTE**
> WebMatrix is no longer recommended as an integrated development environment for ASP.NET Web Pages. Use Visual Studio or Visual Studio Code.

This article lists some frequently asked questions about ASP.NET Web Pages (Razor) and WebMatrix.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3
- Visual Studio 2013
- WebMatrix 3

This tutorial also works with ASP.NET Web Pages 2, WebMatrix 2, and Visual Studio 2012.

- What's the difference between ASP.NET Web Pages, ASP.NET Web Forms, and ASP.NET MVC?
- Do I need WebMatrix in order to work with Web Pages?
- Can I use ASP.NET Web Forms controls on a Web Pages page?
- Can I deploy an ASP.NET Web Pages site without using WebMatrix?
- Do I have to use the WebSecurity helper to support logins?
- Does ASP.NET Web Pages support HTML5?
- Can I use JavaScript and jQuery with Web Pages?
- Additional Resources

For questions about errors and other issues, see the ASP.NET Web Pages (Razor) Troubleshooting Guide.

What's the difference between ASP.NET Web Pages, ASP.NET Web Forms, and ASP.NET MVC?

All three are ASP.NET technologies for creating dynamic web applications:

- ASP.NET Web Pages focuses on adding dynamic (server-side) code and database access to HTML pages, and features simple and lightweight syntax.
- ASP.NET Web Forms is based on a page object model and traditional window-type controls (buttons, lists, etc.). Web Forms uses an event-based model that's familiar to those who've worked with client-based (Windows forms) development.
- ASP.NET MVC implements the model-view-controller pattern for ASP.NET. The emphasis is on "separation of concerns" (processing, data, and UI layers).

All three frameworks are fully supported and continue to be developed by the ASP.NET team. In general, the choice of which framework to use depends on your background and experience with ASP.NET.

ASP.NET Web Pages in particular was designed to make it easy for people who already know HTML to add server processing to their pages. It's a good choice for students, hobbyists, people in general who are new to

programming. It can also be a good choice for developers who have experience with non-ASP.NET web technologies.

Do I need WebMatrix in order to work with Web Pages?

No. WebMatrix is no longer recommended as an integrated development environment for ASP.NET Web Pages. Use Visual Studio or Visual Studio Code.

If you don't want to use either Visual Studio or Visual Studio Code, you can install the component products individually using Microsoft Web Platform Installer. You need the following products:

- Microsoft .NET Framework 4.5
- ASP.NET MVC 5 (which installs the ASP.NET Web Pages framework as well)
- IIS Express (the web server)
- Microsoft SQL Server Compact 4.0 (the database)

You can use a text editor to edit *.cshtml* (or *.vbhtml*) pages.

Managing SQL Server Compact databases (*.sdf* files) without a tool is a bit harder. Visual Studio containds tools for managing *.sdf* databases. You can also run SQL commands in code to perform many SQL Server management tasks.

To test *.cshtml* pages without using an integrated development environment (IDE), you can deploy them to a live server. (See Can I deploy an ASP.NET Web Pages site without using WebMatrix?)

Running IIS Express without using an IDE

If you install IIS Express on your computer as a web server, you can use that to test the pages. You can run IIS Express from the command line and associate it with a specific port number. You then specify that port when you request *.cshtml* files in your browser.

In Windows, open a command prompt with administrator privileges and change to *C:\Program Files\IIS Express.* (For 64-bit systems, use the folder *C:\Program Files (x86)\IIS Express.)* Then enter the following command, using the actual path to your site:

```
iisexpress.exe /port:35896 /path:C:\BasicWebSite
```

You can use any port number that isn't already reserved by some other process. (Port numbers above 1024 are typically free.) For the `path` value, use the path of the website folder where the *.cshtml* files are.

After you run this command to set up IIS Express to serve your pages, you can open a browser and browse to a *.cshtml* file. Use a URL like the following:

```
http://localhost:35896/default.cshtml
```

For help with IIS Express command line options, enter `iisexpress.exe /?` at the command line.

Can I use ASP.NET Web Forms controls on a Web Pages page?

No. Web Forms controls like the CheckBox control, the validation controls, and the GridView control only work in Web Forms pages (*.aspx* files). These controls require the Web Forms page framework.

Can I deploy an ASP.NET Web Pages site without using WebMatrix?

Yes. You can manually copy website files to a server (typically by using FTP). If you perform a manual copy, you also have to copy the files that support SQL Server Compact (the database). For details, see the blog entry Deploying Web Pages applications without a tool.

Do I have to use the WebSecurity helper to support logins?

No. The `SimpleMembership` provider that is part of ASP.NET Web Pages is one option. The security providers that are part of ASP.NET (that you might be used to working with in Web Forms) are also available. For example, you can use forms authentication in ASP.NET Web Pages just as you would in Web Forms. For one example of how to use forms authentication, see the Microsoft Support article How To Implement Forms-Based Authentication in Your ASP.NET Application by Using C#.NET. To download a simple example, see ASP.NET version of "Login & Password.

For information about how to use Windows authentication, see the blog post Using Windows authentication in ASP.NET Web Pages.

Does ASP.NET Web Pages support HTML5?

Yes. The pages you create with ASP.NET Web Pages (*.cshtml* or *.vbhtml* pages) are essentially HTML pages that also contain code that runs on the server, before the page is rendered. As long as the user's browser supports HTML5, you can use HTML5 elements in a *.cshtml* or *.vbhtml* page.

Can I use JavaScript and jQuery with Web Pages?

Absolutely. The pages you create with ASP.NET Web Pages (*.cshtml* or *.vbhtml* pages) are just HTML pages with server code in them. Therefore, anything you can do in a normal HTML page by using JavaScript or jQuery you can also do in a *.cshtml* or *.vbhtml* page.

The **Starter Site** template in WebMatrix contains a number of jQuery libraries. If you create a site by using that template, the *Scripts* folder contains a jQuery core library (*jquery-1.6.2.js)* and libraries for jQuery validation (*jquery.validate.js*, etc.).

Here are some blog posts that illustrate ways to use jQuery with ASP.NET Web Pages:

- Adding jQuery Goodness to ASP.NET Web Pages using WebMatrix by Rachel Appel
- 5 min: WebMatrix + jQuery UI + json + jQuery templates by Jonas Eriksson
- WebMatrix And jQuery Forms by Mike Brind

Sending Email from an ASP.NET Web Pages (Razor) Site

2/20/2020 • 9 minutes to read • Edit Online

by Tom FitzMacken

This article explains how to send an email message from a website when you use ASP.NET Web Pages (Razor).

What you'll learn:

- How to send an email message from your website.
- How to attach a file to an email message.

This is the ASP.NET feature introduced in the article:

- The `WebMail` helper.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

Sending Email Messages from Your Website

There are all sorts of reasons why you might need to send email from your website. You might send confirmation messages to users, or you might send notifications to yourself (for example, that a new user has registered.) The `WebMail` helper makes it easy for you to send email.

To use the `WebMail` helper, you have to have access to an SMTP server. (SMTP stands for *Simple Mail Transfer Protocol*.) An SMTP server is an email server that only forwards messages to the recipient's server — it's the outbound side of email. If you use a hosting provider for your website, they probably set you up with email and they can tell you what your SMTP server name is. If you're working inside a corporate network, an administrator or your IT department can usually give you the information about an SMTP server that you can use. If you're working at home, you might even be able to test using your ordinary email provider, who can tell you the name of their SMTP server. You typically need:

- The name of the SMTP server.
- The port number. This is almost always 25. However, your ISP may require you to use port 587. If you are using secure sockets layer (SSL) for email, you might need a different port. Check with your email provider.
- Credentials (user name, password).

In this procedure, you create two pages. The first page has a form that lets users enter a description, as if they were filling in a technical-support form. The first page submits its information to a second page. In the second page, code extracts the user's information and sends an email message. It also displays a message confirming that the problem report has been received.

NOTE

To keep this example simple, the code initializes the `WebMail` helper right in the page where you use it. However, for real websites, it's a better idea to put initialization code like this in a global file, so that you initialize the `WebMail` helper for all files in your website. For more information, see Customizing Site-Wide Behavior for ASP.NET Web Pages.

1. Create a new website.

2. Add a new page named *EmailRequest.cshtml* and add the following markup:

```
<!DOCTYPE html>
<html>
<head>
    <title>Request for Assistance</title>
</head>
<body>
  <h2>Submit Email Request for Assistance</h2>
  <form method="post" action="ProcessRequest.cshtml">
    <div>
        Your name:
        <input type="text" name="customerName" />
    </div>

    <div>
        Your email address:
        <input type="text" name="customerEmail" />
    </div>

    <div>
        Details about your problem: <br />
        <textarea name="customerRequest" cols="45" rows="4"></textarea>
    </div>

    <div>
        <input type="submit" value="Submit" />
    </div>
  </form>
</body>
</html>
```

   Notice that the `action` attribute of the form element has been set to *ProcessRequest.cshtml*. This means that the form will be submitted to that page instead of back to the current page.

3. Add a new page named *ProcessRequest.cshtml* to the website and add the following code and markup:

```
@{
    var customerName = Request["customerName"];
    var customerEmail = Request["customerEmail"];
    var customerRequest = Request["customerRequest"];
    var errorMessage = "";
    var debuggingFlag = false;
    try {
        // Initialize WebMail helper
        WebMail.SmtpServer = "your-SMTP-host";
        WebMail.SmtpPort = 25;
        WebMail.UserName = "your-user-name-here";
        WebMail.Password = "your-account-password";
        WebMail.From = "your-email-address-here";

        // Send email
        WebMail.Send(to: customerEmail,
            subject: "Help request from - " + customerName,
            body: customerRequest
        );
    }
    catch (Exception ex ) {
        errorMessage = ex.Message;
    }
}
<!DOCTYPE html>
<html>
<head>
  <title>Request for Assistance</title>
</head>
<body>
  <p>Sorry to hear that you are having trouble, <b>@customerName</b>.</p>
    @if(errorMessage == ""){
      <p>An email message has been sent to our customer service
         department regarding the following problem:</p>
      <p><b>@customerRequest</b></p>
    }
    else{
        <p><b>The email was <em>not</em> sent.</b></p>
        <p>Please check that the code in the ProcessRequest page has
           correct settings for the SMTP server name, a user name,
           a password, and a "from" address.
        </p>
        if(debuggingFlag){
            <p>The following error was reported:</p>
            <p><em>@errorMessage</em></p>
        }
    }
</body>
</html>
```

In the code, you get the values of the form fields that were submitted to the page. You then call the `WebMail` helper's `Send` method to create and send the email message. In this case, the values to use are made up of text that you concatenate with the values that were submitted from the form.

The code for this page is inside a `try/catch` block. If for any reason the attempt to send an email doesn't work (for example, the settings aren't right), the code in the `catch` block runs and sets the `errorMessage` variable to the error that has occurred. (For more information about `try/catch` blocks or the `<text>` tag, see Introduction to ASP.NET Web Pages Programming Using the Razor Syntax.)

In the body of the page, if the `errorMessage` variable is empty (the default), the user sees a message that the email message has been sent. If the `errorMessage` variable is set to true, the user sees a message that there's been a problem sending the message.

Notice that in the portion of the page that displays an error message, there's an additional test:

`if(debuggingFlag)`. This is a variable that you can set to true if you're having trouble sending email. When `debuggingFlag` is true, and if there's a problem sending email, an additional error message is displayed that shows whatever ASP.NET has reported when it tried to send the email message. Fair warning, though: the error messages that ASP.NET reports when it can't send an email message can be generic. For example, if ASP.NET can't contact the SMTP server (for example, because you made an error in the server name), the error is `Failure sending mail`.

> **NOTE**
>
> **Important** When you get an error message from an exception object (`ex` in the code), do *not* routinely pass that message through to users. Exception objects often include information that users should not see and that can even be a security vulnerability. That's why this code includes the variable `debuggingFlag` that's used as a switch to display the error message, and why the variable by default is set to false. You should set that variable to true (and therefore display the error message) *only* if you're having a problem with sending email and you need to debug. Once you have fixed any problems, set `debuggingFlag` back to false.

Modify the following email related settings in the code:

- Set `your-SMTP-host` to the name of the SMTP server that you have access to.
- Set `your-user-name-here` to the user name for your SMTP server account.
- Set `your-account-password` to the password for your SMTP server account.
- Set `your-email-address-here` to your own email address. This is the email address that the message is sent from. (Some email providers don't let you specify a different `From` address and will use your user name as the `From` address.)

> **TIP**
>
> **Configuring Email Settings**
>
> It can be a challenge sometimes to make sure you have the right settings for the SMTP server, port number, and so on. Here are a few tips:
>
> - The SMTP server name is often something like `smtp.provider.com` or `smtp.provider.net`. However, if you publish your site to a hosting provider, the SMTP server name at that point might be `localhost`. This is because after you've published and your site is running on the provider's server, the email server might be local from the perspective of your application. This change in server names might mean you have to change the SMTP server name as part of your publishing process.
> - The port number is usually 25. However, some providers require you to use port 587 or some other port.
> - Make sure that you use the right credentials. If you've published your site to a hosting provider, use the credentials that the provider has specifically indicated are for email. These might be different from the credentials you use to publish.
> - Sometimes you don't need credentials at all. If you're sending email using your personal ISP, your email provider might already know your credentials. After you publish, you might need to use different credentials than when you test on your local computer.
> - If your email provider uses encryption, you have to set `WebMail.EnableSsl` to `true`.

4. Run the *EmailRequest.cshtml* page in a browser. (Make sure the page is selected in the **Files** workspace before you run it.)
5. Enter your name and a problem description, and then click the **Submit** button. You're redirected to the *ProcessRequest.cshtml* page, which confirms your message and which sends you an email message.

Sending a File Using Email

You can also send files that are attached to email messages. In this procedure, you create a text file and two HTML pages. You'll use the text file as an email attachment.

1. In the website, add a new text file and name it *MyFile.txt*.

2. Copy the following text and paste it in the file:

```
Lorem ipsum dolor sit amet, consectetur adipisicing elit, sed do eiusmod tempor incididunt ut labore et
dolore magna aliqua. Ut enim ad minim veniam, quis nostrud exercitation ullamco laboris nisi ut aliquip
ex ea commodo consequat.
```

3. Create a page named *SendFile.cshtml* and add the following markup:

```
<!DOCTYPE html>
<html>
<head>
    <title>Attach File</title>
</head>
<body>
  <h2>Submit Email with Attachment</h2>
  <form method="post" action="ProcessFile.cshtml">
    <div>
        Your name:
        <input type="text" name="customerName" />
    </div>

    <div>
        Your email address:
        <input type="text" name="customerEmail" />
    </div>

    <div>
        Subject line: <br />
        <input type="text" size= 30 name="subjectLine" />
    </div>

    <div>
        File to attach: <br />
        <input type="text" size=60 name="fileAttachment" />
    </div>

    <div>
        <input type="submit" value="Submit" />
    </div>
  </form>
</body>
</html>
```

4. Create a page named *ProcessFile.cshtml* and add the following markup:

```
@{
    var customerName = Request["customerName"];
    var customerEmail = Request["customerEmail"];
    var customerRequest = Request["customerRequest"];
    var subjectLine = Request["subjectLine"];
    var fileAttachment = Request["fileAttachment"];
    var errorMessage = "";
    var debuggingFlag = false;

    try {
        // Initialize WebMail helper
        WebMail.SmtpServer = "your-SMTP-host";
        WebMail.SmtpPort = 25;
        WebMail.UserName = "your-user-name-here";
        WebMail.Password = "your-account-password";
        WebMail.From = "your-email-address-here";

        // Create array containing file name
        var filesList = new string [] { fileAttachment };

        // Attach file and send email
        WebMail.Send(to: customerEmail,
            subject: subjectLine,
            body: "File attached. <br />From: " + customerName,
            filesToAttach: filesList);
    }
    catch (Exception ex ) {
        errorMessage = ex.Message;
    }
}
<!DOCTYPE html>
<html>
<head>
    <title>Request for Assistance</title>
</head>
<body>
  <p>Sorry to hear that you are having trouble, <b>@customerName</b>.</p>
    @if(errorMessage == ""){
        <p><b>@customerName</b>, thank you for your interest.</p>
        <p>An email message has been sent to our customer service
           department with the <b>@fileAttachment</b> file attached.</p>
    }
    else{
        <p><b>The email was <em>not</em> sent.</b></p>
        <p>Please check that the code in the ProcessRequest page has
           correct settings for the SMTP server name, a user name,
           a password, and a "from" address.
        </p>
        if(debuggingFlag){
            <p>The following error was reported:</p>
            <p><em>@errorMessage</em></p>
        }
    }
</body>
</html>
```

5. Modify the following email related settings in the code from the example:

- Set `your-SMTP-host` to the name of an SMTP server that you have access to.
- Set `your-user-name-here` to the user name for your SMTP server account.
- Set `your-email-address-here` to your own email address. This is the email address that the message is sent from.
- Set `your-account-password` to the password for your SMTP server account.
- Set `target-email-address-here` to your own email address. (As before, you'd normally send an email to

someone else, but for testing, you can send it to yourself.)

6. Run the *SendFile.cshtml* page in a browser.

7. Enter your name, a subject line, and the name of the text file to attach (*MyFile.txt*).

8. Click the `Submit` button. As before, you're redirected to the *ProcessFile.cshtml* page, which confirms your message and which sends you an email message with the attached file.

Adding Social Networking to ASP.NET Web Pages (Razor) Sites

2/20/2020 • 5 minutes to read • Edit Online

by Tom FitzMacken

This article explains how to add social networking links for Facebook, Twitter, Reddit, and Digg to pages in an ASP.NET Web Pages (Razor) website, and how to include Twitter feeds, Xbox gamer cards, and Gravatar images.

What you'll learn:

- How to let people bookmark/link your site.
- How to add a Twitter feed.
- How to add a Facebook **Like** button to pages.
- How to render Gravatar.com images.
- How to display an Xbox gamer card on your site.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- ASP.NET Web Helper Library (NuGet package)

This tutorial also works with ASP.NET Web Pages 3, except for parts that use the ASP.NET Web Helper Library.

Linking Your Website on Social Networking Sites

If people like something on your site, they often want to share it with friends. You can make this easy by displaying glyphs (icons) that people can click to share a page on Digg, Reddit, Facebook, Twitter, or similar sites.

To display these glyphs, add the `LinkSharecode` helper to a page. People who visit your page can click an individual glyph. If they have an account with that social networking site, they can then post a link to your page on that site.

1. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already added it.- Create a page named *ListLinkShare.cshtml* and add the following markup:

```
@using Microsoft.Web.Helpers;

<!DOCTYPE html>
<html>
  <head>
    <title>LinkShare Example</title>
  </head>
  <body>
    <h1>LinkShare Example</h1>
    Share: @LinkShare.GetHtml("LinkShare Example", linkSites: new[]{
        LinkShareSite.Reddit, LinkShareSite.Facebook, LinkShareSite.Twitter})
  </body>
</html>
```

In this example, when the `LinkShare` helper runs, the page title is passed as a parameter, which in turn passes the page title to the social networking site. However, you could pass in any string you want. This example also specifies which social networking sites to include in the list. You can specify the social networking sites that are relevant to your site.

2. Run the *ListLinkShare.cshtml* page in a browser. (Make sure the page is selected in the **Files** workspace before you run it.)

3. Click a glyph for one of the sites that you're signed up for. The link takes you to the page on the selected social network site where you can share a link. For example, if you click the Reddit link, you're taken to the `submit to reddit` page on the Reddit website.

Adding a Twitter Feed

For information about using a Twitter helper that is compatible with the current version of the Twitter API, see Twitter helper. This example shows how to write your own helper so you can easily reuse the code from many pages.

Displaying a Facebook "Like" Button

In some cases, your best option is to get the code directly from the social networking provider rather than relying on a helper. This is especially true if the social network provider updates its options more quickly than the helper is

updated.

To add Facebook features (such as the Like button) to your site, you can retrieve code snippets from the developers.facebook.com site. On the Facebook site, you use their tools to generate a code snippet that is relevant to your site.

The following highlighted code is the code that was retrieved from the Like Button tool on the developers.facebook.com site. You must provide your own app ID.

```
<!DOCTYPE html>
<html>
  <head>
    <title>Facebook Like Example</title>
  </head>
  <body>
    <div id="fb-root"></div>
    <script>(function(d, s, id) {
        var js, fjs = d.getElementsByTagName(s)[0];
        if (d.getElementById(id)) return;
        js = d.createElement(s); js.id = id;
        js.src = "//connect.facebook.net/en_US/all.js#xfbml=1&appId=<provide appId>";
        fjs.parentNode.insertBefore(js, fjs);
      }(document, 'script', 'facebook-jssdk'));</script>
    <h1>Facebook Like Example</h1>
    <div class="fb-like" data-href="/web-pages/overview" data-layout="standard"
        data-action="like" data-show-faces="true" data-share="true"></div>
  </body>
</html>
```

Rendering a Gravatar Image

A *Gravatar* (a "globally recognized avatar") is an image that can be used on multiple websites as your avatar — that is, an image that represents you. For example, a Gravatar can identify a person in a forum post, in a blog comment, and so on. (You can register your own Gravatar at the Gravatar website at http://www.gravatar.com/.) If you want to display images next to people's names or email addresses on your website, you can use the Gravatar helper.

In this example, you're using a single Gravatar that represents yourself. Another way to use a Gravatar is to let people specify their Gravatar address when they register on your site. (You can learn how to let people register in Adding Security and Membership to an ASP.NET Web Pages Site.) Then whenever you display information for that user, you can just add the Gravatar to where you display the user's name.

1. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already.

2. Create a new web page named *Gravatar.cshtml*.

3. Add the following markup to the file:

```
@using Microsoft.Web.Helpers;
<!DOCTYPE html>
<html>
    <head>
        <title>Gravatar Example</title>
    </head>
    <body>
        <h1>Gravatar Example</h1>
        @Gravatar.GetHtml("<Your Gravatar account here>")
           
        @Gravatar.GetHtml("<Your Gravatar account here>", 40)
    </body>
</html>
```

The `Gravatar.GetHtml` method displays the Gravatar image on the page. To change the size of the image, you can include a number as a second parameter. The default size is 80. Numbers less than 80 make the image smaller. Numbers greater than 80 make the image larger.

4. In the `Gravatar.GetHtml` methods, replace `<Your Gravatar account here>` with the email address that you use for your Gravatar account. (If you don't have a Gravatar account, you can use the email address of someone who does.)

5. Run the page in your browser. The page displays two Gravatar images for the email address you specified. The second image is smaller than the first.

Displaying an Xbox Gamer Card

When people play Microsoft Xbox games online, each user has a unique ID. Statistics are kept for each player in the form of a gamer card, which shows their reputation, gamer score, and recently played games. If you're an Xbox gamer, you can show your gamer card on pages in your site by using the `GamerCard` helper.

1. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already.

2. Create a new page named *XboxGamer.cshtml* and add the following markup.

```
@using Microsoft.Web.Helpers;
<!DOCTYPE html>
<html>
  <head>
    <title>Xbox Gamer Card</title>
  </head>
  <body>
    <h1>Xbox Gamer Card</h1>
    @GamerCard.GetHtml("major nelson")
  </body>
</html>
```

You use the `GamerCard.GetHtml` property to specify the alias for the gamer card to be displayed.

3. Run the page in your browser. The page displays the Xbox gamer card that you specified.

Introducing ASP.NET Web Pages

Introducing ASP.NET Web Pages 2

- Getting Started
- Programming Basics
- Displaying Data
- HTML Form Basics
- Entering Database Data by Using Forms
- Updating Database Data
- Deleting Database Data
- Creating a Consistent Layout
- Publishing a Site by Using WebMatrix

Getting Started

9/16/2020 • 13 minutes to read • Edit Online

by Tom FitzMacken

For new web application development, we recommend Razor Pages. For more information, see Get started with Razor Pages.

> **NOTE**
> WebMatrix is no longer recommended as an integrated development environment for ASP.NET Web Pages. Use Visual Studio or Visual Studio Code.

This guidance and application gives you an overview of ASP.NET Web Pages (version 2 or later) and Razor syntax, a lightweight framework for creating dynamic websites. It also introduces WebMatrix, a tool for creating pages and sites.

Level: New to ASP.NET Web Pages.
Skills assumed: HTML, basic cascading style sheets (CSS).

What you'll learn in the first tutorial of the set:

- What ASP.NET Web Pages technology is and what it's for.
- What WebMatrix is.
- How to install everything.
- How to create a website by using WebMatrix.

Features/technologies discussed:

- Microsoft Web Platform Installer.
- WebMatrix.
- *.cshtml* pages

Mike Pope originally wrote this tutorial. Tom FitzMacken updated it for Microsoft WebMatrix 3.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- WebMatrix 3

What Should You Know?

We're assuming that you're familiar with:

- **HTML**. No in-depth expertise is required. We won't explain HTML, but we also don't use anything complex. We'll provide links to HTML tutorials where we think they're useful.
- **Cascading style sheets (CSS)**. Same as with HTML.
- **Basic database ideas**. If you've used a spreadsheet for data and sorted and filtered the data, that's the level of expertise we're generally assuming for this tutorial set.

We're also assuming that you're interested in learning basic programming. ASP.NET Web Pages use a

programming language called C#. You don't have to have any background in programming, just an interest in it. If you've ever written any JavaScript in a web page before, you've got plenty of background.

Note that if you are familiar with programming, you might find that this tutorial set initially moves slowly while we bring new programmers up to speed. As we get past the first few tutorials, though, there will be less basic programming to explain and things will move along at a faster clip.

What Do You Need?

Here's what you'll need:

- A computer that is running Windows 8, Windows 7, Windows Server 2008, or Windows Server 2012.
- A live internet connection.
- Administrator privileges (required for the installation process).

What Is ASP.NET Web Pages?

ASP.NET Web Pages is a framework that you can use to create dynamic web pages. A simple HTML web page is static; its content is determined by the fixed HTML markup that's in the page. Dynamic pages like those you create with ASP.NET Web Pages let you create the page content on the fly, by using code.

Dynamic pages let you do all sorts of things. You can ask a user for input by using a form and then change what the page displays or how it looks. You can take information from a user, save it in a database, and then list it later. You can send email from your site. You can interact with other services on the web (for example, a mapping service) and produce pages that integrate information from those sources.

What is WebMatrix?

WebMatrix is a tool that integrates a web page editor, a database utility, a web server for testing pages, and features for publishing your website to the Internet. WebMatrix is free, and it's easy to install and easy to use. (It also works for just plain HTML pages, as well as for other technologies like PHP.)

You don't actually *have* to use WebMatrix to work with ASP.NET Web Pages. You can create pages by using a text editor, for example, and test pages by using a web server that you have access to. However, WebMatrix makes it all very easy, so these tutorials will use WebMatrix throughout.

About These Tutorials

This tutorial set is an introduction to how to use ASP.NET Web Pages. There are 9 tutorials total in this introductory tutorial set. It's part of a series of tutorial sets that takes you from ASP.NET Web Pages novice to creating real, professional-looking websites.

This first tutorial set concentrates on showing you the basics of how to work with ASP.NET Web Pages. When you're done, you can work with additional tutorial sets that pick up where this one ends and that explore Web Pages in more depth.

We deliberately go easy on the in-depth explanations. And whenever we show something, for this tutorial set we always choose the way that we think is easiest to understand. Later tutorial sets go into more depth and show you more efficient or more flexible approaches (also more fun). But those tutorials require you to understand the basics first.

The tutorial set you've just started covers these features of ASP.NET Web Pages:

- Introduction and getting everything installed. (That's in the tutorial you're reading.)
- The basics of ASP.NET Web Pages programming.
- Creating a database.

- Creating and processing a user input form.
- Adding, updating, and deleting data in the database.

What Will You Create?

This tutorial set and subsequent ones revolve around a website where you can list movies that you like. You'll be able to enter movies, edit them, and list them. Here are a couple of the pages you'll create in this tutorial set. The first one shows the movie listing page that you'll create:

And here's the page that lets you add new movie information to your site:

Subsequent tutorial sets build on this set and add more functionality, like uploading pictures, letting people log in, sending email, and integrating with social media.

See this App Running on Azure

Would you like to see the finished site running as a live web app? You can deploy a complete version of the app to your Azure account by simply clicking the following button.

Deploy to Azure

You need an Azure account to deploy this solution to Azure. If you do not already have an account, you have the following options:

- Open an Azure account for free - You get credits you can use to try out paid Azure services, and even after they're used up you can keep the account and use free Azure services.
- Activate MSDN subscriber benefits - Your MSDN subscription gives you credits every month that you can use for paid Azure services.

Installing Everything

You can install everything by using the Web Platform Installer from Microsoft. In effect, you install the installer, and then use it to install everything else.

To use Web Pages, you have to be have at least Windows XP with SP3 installed, or Windows Server 2008 or later.

On the Web Pages page of the ASP.NET website, click **Install**.

You are asked to accept the license terms and privacy statement before installing WebMatrix.

Click **Run** to start the installation. (If you want to save the installer, click **Save** and then run the installer from the folder where you saved it.)

The Web Platform Installer appears, ready to install WebMatrix. Click **Install**.

The installation process figures out what it has to install on your computer and starts the process. Depending on what exactly has to be installed, the process can take anywhere from a few moments to several minutes. Select **I Accept** to accept the license terms.

Hello, WebMatrix

When it's done, the installation process can launch WebMatrix automatically. If it doesn't, in Windows, from the **Start** menu, launch **Microsoft WebMatrix**.

When you launch WebMatrix for the first time, you are given a chance to sign in to Microsoft Azure with your Microsoft account. By signing in, you will receive 10 free web apps through Azure. These free web apps provide a convenient way to test your apps. If you don't already have an Azure account, but you do have an MSDN subscription, you can activate your MSDN subscription benefits. Otherwise, you can create a free trial account in just a couple of minutes. For details, see Azure Free Trial.

You do not have to sign in right now to continue with this tutorial. If you do not sign in now, you will still have the option to sign in later. The last topic in this tutorial series covers how to deploy your website to Azure; therefore, you would need to sign in to complete that topic.

At this point, either sign in with your Microsoft account or select **Not Now** in the lower right corner.

To begin, you'll create a blank website and add a page. In a later tutorial in this set you'll play with one of the built-in website templates.

In the start window, click **New**.

Templates are prebuilt files and pages for different types of websites. To see all of the templates that are available by default, select the Template Gallery option.

In the **Quick Start** window, select **Empty Site** from the **ASP.NET** group and name the new site "WebPagesMovies".

Click **Next**.

If you have signed in to your Microsoft account, you will be given the opportunity to create the site on Azure. Based on the name of your site, the default name of **WebPagesMovies.azurewebsites.net** is suggested; however, the exclamation point indicates that this name is not available on Windows Azure. For simplicity, select **Skip** to bypass creating the web site on Azure right now. Later in this series, we will publish the site to Azure.

WebMatrix creates and opens the site:

At the top, there's a Quick Access Toolbar and a ribbon. At the bottom left, you see the workspace selector where you switch between tasks (**Site**, **Files**, **Databases**, **Reports**). On the right is the content pane for the editor and for reports. And across the bottom you'll occasionally see a notification bar for messages.

You'll learn more about WebMatrix and its features as you go through these tutorials.

Creating a Web Page

To become familiar with WebMatrix and ASP.NET Web Pages, you'll create a simple page.

In the workspace selector, select the **Files** workspace. This workspace lets you work with files and folders. The left pane shows the file structure of your site. The ribbon changes to show file-related tasks.

In the ribbon, click the arrow under **New** and then click **New File**.

WebMatrix displays a list of file types. Select **CSHTML**, and in the **Name** box, type "HelloWorld". A CSHTML page is an ASP.NET Web Pages page.

Click **OK**.

WebMatrix creates the page and opens it in the editor.

As you can see, the page contains mostly ordinary HTML markup, except for a block at the top that looks like this:

```
@{

}
```

That's for adding code, as you'll see shortly.

Notice that the different parts of the page — the element names, attributes, and text, plus the block at the top — are all in different colors. This is called *syntax highlighting*, and it makes it easier to keep everything clear. It's one of the features that makes it easy to work with web pages in WebMatrix.

Add content for the `<head>` and `<body>` elements like in the following example. (If you want, you can just copy the following block and replace the entire existing page with this code.)

```
@{

}

<!DOCTYPE html>

<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title>Hello World Page</title>
    </head>
    <body>
        <h1>Hello World Page</h1>
        <p>Hello World!</p>
    </body>
</html>
```

In the Quick Access Toolbar or in the **File** menu, click **Save**.

Testing the Page

In the **Files** workspace, right-click the *HelloWorld.cshtml* page and then click **Launch in browser**.

WebMatrix starts a built-in web server (IIS Express) that you can use to test pages on your computer. (Without IIS Express in WebMatrix, you'd have to publish your page to a web server somewhere before you could test it.) The page is displayed in your default browser.

Notice that when you test a page in WebMatrix, the URL in the browser is something like `http://localhost:33651/HelloWorld.cshtml.` The name *localhost* refers to a local server, meaning that the page is served by a web server that's on your own computer. As noted, WebMatrix includes a web server program named IIS Express that runs when you launch a page.

The number after *localhost* (for example, *localhost:33651*) refers to a *port number* on your computer. This is the number of the "channel" that IIS Express uses for this particular website. The port number is selected at random from the range 1024 through 65536 when you create your site, and it's different for every site that you create. (When you test your own site, the port number will almost certainly be a different number than 33561.) By using a different port for each website, IIS Express can keep straight which of your sites it's talking to.

Later when you publish your site to a public web server, you no longer see *localhost* in the URL. At that point, you'll see a more typical URL like `http://myhostingsite/mywebsite/HelloWorld.cshtml` or whatever the page is. You'll learn more about publishing a site later in this tutorial series.

Adding Some Server-Side Code

Close the browser and go back to the page in WebMatrix.

Add a line to the code block so that it looks like the following code:

```
@{
   var currentDateTime = DateTime.Now;
}
```

This is a little bit of Razor code. It's probably clear that it gets the current date and time and puts that value into a *variable* named `currentDateTime`. You'll read more about Razor syntax in the next tutorial.

In the body of the page, after the `<p>Hello World!</p>` element, add the following:

```
<p>Right now it's @currentDateTime</p>
```

This code gets the value that you put into the `currentDateTime` variable at the top and inserts it into the markup of the page. The `@` character marks the ASP.NET Web Pages code in the page.

Run the page again (WebMatrix saves the changes for you before it runs the page). This time you see the date and time in the page.

Wait a few moments and then refresh the page in the browser. The date and time display is updated.

In the browser, look at the page source. It looks like the following markup:

```
<!DOCTYPE html>

<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title>Hello World Page</title>
    </head>
    <body>
        <h1>Hello World Page</h1>
        <p>Hello World!</p>
        <p>Right now it's 1/18/2012 2:49:50 PM</p>
    </body>
</html>
```

Notice that the `@{ }` block at the top isn't there. Also notice that the date and time display shows an actual string of characters (`1/18/2012 2:49:50 PM` or whatever), not `@currentDateTime` like you had in the *.cshtml* page. What happened here is that when you ran the page, ASP.NET processed all the code (very little in this case) that was marked with `@`. The code produces output, and that output was inserted into the page.

This Is What ASP.NET Web Pages Are About

When you read that ASP.NET Web Pages produces dynamic web content, what you've seen here is the idea. The page you just created contains the same HTML markup that you've seen before. It can also contain code that can perform all sorts of tasks. In this example, it did the trivial task of getting the current date and time. As you saw, you can intersperse code with the HTML to produce output in the page. When someone requests a *.cshtml* page in the browser, ASP.NET processes the page while it's still in the hands of the web server. ASP.NET inserts the output of the code (if any) into the page as HTML. When the code processing is done, ASP.NET sends the resulting page to the browser. All the browser ever gets is HTML. Here's a diagram:

The idea is simple, but there are many interesting tasks that the code can perform, and there are many interesting ways in which you can dynamically add HTML content to the page. And ASP.NET *.cshtml* pages, like any HTML page, can also include code that runs in the browser itself (JavaScript and jQuery code). You'll explore all of these things in this tutorial set and in subsequent ones.

Coming Up Next

In the next tutorial in this series, you explore ASP.NET Web Pages programming a little more.

Additional Resources

Create an ASP.NET website from scratch. This is a tutorial that's specifically about using WebMatrix (not ASP.NET Web Pages). It goes into a little more detail about some of the additional features of WebMatrix that we won't cover in this tutorial set.

Introducing ASP.NET Web Pages - Programming Basics

2/20/2020 • 24 minutes to read • Edit Online

by Tom FitzMacken

This tutorial gives you an overview of how to program in ASP.NET Web Pages with Razor syntax.

What you'll learn:

- The basic "Razor" syntax that you use for programming in ASP.NET Web Pages.
- Some basic C#, which is the programming language you'll use.
- Some fundamental programming concepts for Web Pages.
- How to install packages (components that contain prebuilt code) to use with your site.
- How to use *helpers* to perform common programming tasks.

Features/technologies discussed:

- NuGet and the package manager.
- The `Gravatar` helper.

This tutorial is primarily an exercise in introducing you to the programming syntax that you'll use for ASP.NET Web Pages. You'll learn about *Razor syntax* and code that's written in the C# programming language. You got a glimpse of this syntax in the previous tutorial; in this tutorial we'll explain the syntax more.

We promise that this tutorial involves the most programming that you'll see in a single tutorial, and that it's the only tutorial that is *only* about programming. In the remaining tutorials in this set, you'll actually create pages that do interesting things.

You'll also learn about *helpers*. A helper is a component — a packaged-up piece of code — that you can add to a page. The helper performs work for you that otherwise might be tedious or complex to do by hand.

Creating a Page to Play with Razor

In this section you'll play a bit with Razor so you can get a sense of the basic syntax.

Start WebMatrix if it's not already running. You'll use the website you created in the previous tutorial (Getting Started With Web Pages). To reopen it, click **My Sites** and choose **WebPageMovies**:

Select the **Files** workspace.

In the ribbon, click **New** to create a page. Select **CSHTML** and name the new page *TestRazor.cshtml*.

Click **OK**.

Copy the following into the file, completely replacing what's there already.

> **NOTE**
> When you copy code or markup from the examples into a page, the indentation and alignment might not be the same as in the tutorial. Indentation and alignment don't affect how the code runs, though.

```
@{
   // Working with numbers
   var a = 4;
   var b = 5;
   var theSum = a + b;

   // Working with characters (strings)
   var technology = "ASP.NET";
   var product ="Web Pages";

   // Working with objects
   var rightNow = DateTime.Now;
}

<!DOCTYPE html>
<html lang="en">
  <head>
    <title>Testing Razor Syntax</title>
    <meta charset="utf-8" />
    <style>
    body {font-family:Verdana; margin-left:50px; margin-top:50px;}
    div {border: 1px solid black; width:50%; margin:1.2em;padding:1em;}
    span.bright {color:red;}
    </style>
  </head>
<body>
  <h1>Testing Razor Syntax</h1>
  <form method="post">

    <div>
      <p>The value of <em>a</em> is @a.  The value of <em>b</em> is @b.
      <p>The sum of <em>a</em> and <em>b</em> is <strong>@theSum</strong>.</p>
      <p>The product of <em>a</em> and <em>b</em> is <strong>@(a*b)</strong>.</p>
    </div>

    <div>
      <p>The technology is @technology, and the product is @product.</p>
      <p>Together they are <span class="bright">@(technology + " " + product)</span></p>
   </div>

   <div>
     <p>The current date and time is: @rightNow</p>
     <p>The URL of the current page is<br/><br/><code>@Request.Url</code></p>
   </div>

  </form>
</body>
</html>
```

Examining the Example Page

Most of what you see is ordinary HTML. However, at the top there's this code block:

```
@{
   // Working with numbers.
   var a = 4;
   var b = 5;
   var theSum = a + b;

   // Working with characters (strings).
   var technology = "ASP.NET";
   var product ="Web Pages";

   // Working with objects.
   var rightNow = DateTime.Now;
}
```

Notice the following things about this code block:

- The @ character tells ASP.NET that what follows is Razor code, not HTML. ASP.NET will treat everything after the @ character as code until it runs into some HTML again. (In this case, that's the <!DOCTYPE> element.
- The braces ({ and }) enclose a block of Razor code if the code has more than one line. The braces tell ASP.NET where the code for that block starts and ends.
- The // characters mark a comment — that is, a part of the code that won't execute.
- Each statement has to end with a semicolon (;). (Not comments, though.)
- You can store values in *variables*, which you create (*declare*) with the keyword var. When you create a variable, you give it a name, which can include letters, numbers, and underscore (_). Variable names can't start with a number and can't use the name of a programming keyword (like var).
- You enclose character strings (like "ASP.NET" and "Web Pages") in quotation marks. (They must be double quotation marks.) Numbers are not in quotation marks.
- Whitespace outside of quotation marks doesn't matter. Line breaks mostly don't matter; the exception is that you can't split a string in quotation marks across lines. Indentation and alignment don't matter.

Something that's not obvious from this example is that all code is case sensitive. This means that the variable TheSum is a different variable than variables that might be named theSum or thesum. Similarly, var is a keyword, but Var is not.

Objects and properties and methods

Then there's the expression DateTime.Now. In simple terms, DateTime is an *object*. An object is a thing that you can program with—a page, a text box, a file, an image, a web request, an email message, a customer record, etc. Objects have one or more *properties* that describe their characteristics. A text box object has a Text property (among others), a request object has a Url property (and others), an email message has a From property and a To property, and so on. Objects also have *methods* that are the "verbs" they can perform. You'll be working with objects a lot.

As you can see from the example, DateTime is an object that lets you program dates and times. It has a property named Now that returns the current date and time.

Using code to render markup in the page

In the body of the page, notice the following:

```
<div>
  <p>The value of <em>a</em> is @a.  The value of <em>b</em> is @b.
  <p>The sum of <em>a</em> and <em>b</em> is <strong>@theSum</strong>.</p>
  <p>The product of <em>a</em> and <em>b</em> is <strong>@(a*b)</strong>.</p>
</div>

<div>
  <p>The technology is @technology, and the product is @product.</p>
  <p>Together they are <span class="bright">@(technology + " " + product)</span></p>
</div>

<div>
  <p>The current date and time is: @rightNow</p>
     <p>The URL of the current page is<br/><br/><code>@Request.Url</code></p>
</div>
```

Again, the @ character tells ASP.NET that what follows is code, not HTML. In the markup you can add @ followed by a code expression, and ASP.NET will render the value of that expression right at that point. In the example, @a will render whatever the value is of the variable named a, @product renders whatever is in the variable named product, and so on.

You're not limited to variables, though. In a few instances here, the @ character precedes an expression:

- @(a*b) renders the product of whatever is in the variables a and b. (The * operator means multiplication.)
- @(technology + " " + product) renders the values in the variables technology and product after concatenating them and adding a space in between. The operator (+) for concatenating strings is the same as the operator for adding numbers. ASP.NET can usually tell whether you're working with numbers or with strings and does the right thing with the + operator.
- @Request.Url renders the Url property of the Request object. The Request object contains information about the current request from the browser, and of course the Url property contains the URL of that current request.

The example is also designed to show you that you can do work in different ways. You can do calculations in the code block at the top, put the results into a variable, and then render the variable in markup. Or you can do calculations in an expression right in the markup. The approach you use depends on what you're doing and, to some extent, on your own preference.

Seeing the code in action

Right-click the name of the file and then choose **Launch in browser**. You see the page in the browser with all the values and expressions resolved in the page.

Look at the source in the browser.

```
<!DOCTYPE html>
<html lang="en">
  <head>
    <title>Testing Razor Syntax</title>
    <meta charset="utf-8" />
    <style>
    body {font-family:Verdana; margin-left:50px; margin-top:50px;}
    div {border: 1px solid black; width:50%; margin:1.2em;padding:1em;}
    span.bright {color:red;}
    </style>
  </head>
<body>
  <h1>Testing Razor Syntax</h1>
  <form method="post">

    <div>
      <p>The value of <em>a</em> is 4.  The value of <em>b</em> is 5.
      <p>The sum of <em>a</em> and <em>b</em> is <strong>9</strong></p>
      <p>The product of <em>a</em> and <em>b</em> is <strong>20</strong></p>
    </div>

    <div>
      <p>The technology is ASP.NET, and the product is Web Pages.</p>
      <p>Together they are <span class="bright">ASP.NET Web Pages</span></p>
   </div>

   <div>
     <p>The current date and time is: 4/29/2012 11:44:02 PM</p>
     <p>The URL of the current page is <code>http://localhost:45661/TestRazor.cshtml</code></p>
   </div>

  </form>
</body>
</html>
```

As you expect from your experience in the previous tutorial, none of the Razor code is in the page. All you see are the actual display values. When you run a page, you're actually making a request to the web server that's built into WebMatrix. When the request is received, ASP.NET resolves all the values and expressions and renders their values into the page. It then sends the page to the browser.

TIP

Razor and C#

Up to now we've said that you're working with Razor syntax. That's true, but it's not the complete story. The actual programming language you're using is called *C#*. C# was created by Microsoft over a decade ago and has become one of the primary programming languages for creating Windows apps. All the rules you've seen about how to name a variable and how to create statements and so on are actually all rules of the C# language.

Razor refers more specifically to the small set of conventions for how you embed this code into a page. For example, the convention of using @ to mark code in the page and using @{ } to embed a code block is the Razor aspect of a page. Helpers are also considered to be part of Razor. Razor syntax is used in more places than just in ASP.NET Web Pages. (For example, it's used in ASP.NET MVC views as well.)

We mention this because if you look for information about programming ASP.NET Web Pages, you'll find lots of references to Razor. However, a lot of those references don't apply to what you're doing and might therefore be confusing. And in fact, many of your programming questions are really going to be about either working with C# or working with ASP.NET. So if you look specifically for information about Razor, you might not find the answers you need.

Adding Some Conditional Logic

One of the great features about using code in a page is that you can change what happens based on various conditions. In this part of the tutorial, you'll play around with some ways to change what's displayed in the page.

The example will be simple and somewhat contrived so that we can concentrate on the conditional logic. The page you'll create will do this:

- Show different text on the page depending on whether it's the first time the page is displayed or whether you've clicked a button to submit the page. That will be the first conditional test.
- Display the message only if a certain value is passed in the query string of the URL (http://...?show=true). That will be the second conditional test.

In WebMatrix, create a page and name it *TestRazorPart2.cshtml*. (In the ribbon, click **New**, choose **CSHTML**, name the file, and then click **OK**.)

Replace the contents of that page with the following:

```
@{
   var message = "This is the first time you've requested the page.";
}
<!DOCTYPE html>
<html lang="en">
  <head>
    <title>Testing Razor Syntax - Part 2</title>
    <meta charset="utf-8" />
    <style>
      body {font-family:Verdana; margin-left:50px; margin-top:50px;}
      div {border: 1px solid black; width:50%; margin:1.2em;padding:1em;}
    </style>
  </head>
  <body>
  <h1>Testing Razor Syntax - Part 2</h1>
  <form method="post">
    <div>
      <p>@message</p>
      <p><input type="submit" value="Submit" /></p>
  </div>
  </form>
</body>
</html>
```

The code block at the top initializes a variable named message with some text. In the body of the page, the contents of the message variable are displayed inside a <p> element. The markup also contains an <input> element to create a **Submit** button.

Run the page to see how it works now. For now, it's basically a static page, even if you click the **Submit** button.

Go back to WebMatrix. Inside the code block, add the following highlighted code *after* the line that initializes message:

```
@{
    var message = "This is the first time you've requested the page.";

    if(IsPost) {
        message = "Now you've submitted the page.";
    }
}
```

The if { } block

What you just added was an if condition. In code, the if condition has a structure like this:

```
if(some condition){
    One or more statements here that run if the condition is true;
}
```

The condition to test is in parentheses. It has to be a value or an expression that returns true or false. If the condition is true, ASP.NET runs the statement or statements that are inside the braces. (Those are the *then* part of the *if-then* logic.) If the condition is false, the block of code is skipped.

Here are a few examples of conditions you can test in an if statement:

```
if(currentValue > 12) { ... }

if(dueDate <= DateTime.Today) { ... }

if(IsDone == true) { ... }

if(IsPost) { ... }

if(!IsPost) { ... }

if(a != 0) { ... }

if(fileProcessingIsDone != true && displayMessage == false) { ... }
```

You can test variables against values or against expressions by using a *logical operator* or *comparison operator*: equal to (==), greater than (>), less than (<), greater than or equal to (>=), and less than or equal to (<=). The != operator means not equal to — for example, if(a != 0) means *if a is not equal to 0*.

> **NOTE**
> Make sure you notice that the comparison operator for equals to (==) is not the same as =. The = operator is used only to assign values (var a=2). If you mix these operators up, you'll either get an error or you'll get some strange results.

To test whether something is true, the complete syntax is if(IsDone == true). But you can also use the shortcut if(IsDone). If there's no comparison operator, ASP.NET assumes that you're testing for true.

The ! operator by itself means a logical NOT. For example, the condition if(!IsPost) means *if IsPost is not true*.

You can combine conditions by using a logical AND (&& operator) or logical OR (|| operator). For example, the last of the if conditions in the preceding examples means *if FileProcessingIsDone is not set to true AND displayMessage is set to false*.

The else block

One final thing about if blocks: an if block can be followed by an else block. An else block is useful is you have to execute different code when the condition is false. Here's a simple example:

```
var message = "";
if(errorOccurred == true)
{
    message = "Sorry, an error occurred.";
}
else
{
    message = "The process finished without errors!";
}
```

You'll see some examples in later tutorials in this series where using an else block is useful.

Testing whether the request is a submit (post)

There's more, but let's get back to the example, which has the condition if(IsPost){ ... }. IsPost is actually a property of the current page. The first time the page is requested, IsPost returns false. However, if you click a button or otherwise submit the page — that is, you post it — IsPost returns true. So IsPost lets you determine whether you're dealing with a form submission. (In terms of HTTP verbs, if the request is a GET operation, IsPost returns false. If the request is a POST operation, IsPost returns true.) In a later tutorial you'll work with input forms, where this test becomes particularly useful.

Run the page. Because this is the first time you're requested the page, you see "This is the first time you've

requested the page". That string is the value that you initialized the message variable to. There's an if(IsPost) test, but that returns false at the moment, so the code inside the if block doesn't run.

Click the **Submit** button. The page is requested again. As before, the message variable is set to "This is the first time ...". But this time, the test if(IsPost) returns true, so the code inside the if block runs. The code changes the value of the message variable to a different value, which is what's rendered in the markup.

Now add an if condition in the markup. Below the <p> element that contains the **Submit** button, add the following markup:

```
@if(IsPost){
  <p>You submitted the page at @DateTime.Now</p>
}
```

You're adding code inside the markup, so you have to start with @. Then there's an if test similar to the one you added earlier up in the code block. Inside the braces, though, you're adding ordinary HTML — at least, it's ordinary until it gets to @DateTime.Now. This is another little bit of Razor code, so again you have to add @ in front of it.

The point here is that you can add if conditions in both the code block at the top and in the markup. If you use an if condition in the body of the page, the lines inside the block can be markup or code. In that case, and as is true anytime you mix markup and code, you have to use @ to make it clear to ASP.NET where the code is.

Run the page and click **Submit**. This time you not only see a different message when you submit ("Now you've submitted ..."), but you see a new message that lists the date and time.

Testing the value of a query string

One more test. This time, you'll add an if block that tests a value named show that might be passed in the query string. (Like this: `http://localhost:43097/TestRazorPart2.cshtml?show=true`) You'll change the page so that the message you've been displaying ("This is the first time ...", etc.) is only displayed if the value of show is true.

At the bottom (but inside) the code block at the top of the page, add the following:

```
var showMessage = false;
if(Request.QueryString["show"].AsBool() == true) {
    showMessage = true;
}
```

The complete code block now look like the following example. (Remember that when you copy the code into your page, the indentation might look different. But that doesn't affect how the code runs.)

```
@{
   var message = "This is the first time you've requested the page.";

   if(IsPost) {
      message = "Now you've submitted the page.";
   }

   var showMessage = false;
   if(Request.QueryString["show"].AsBool() == true) {
     showMessage = true;
   }
}
```

The new code in the block initializes a variable named showMessage to false. It then does an if test to look for a value in the query string. When you first request the page, it has a URL like this one:

`http://localhost:43097/TestRazorPart2.cshtml`

The code determines whether the URL contains a variable named show in the query string, like this version of the URL:

`http://localhost:43097/TestRazorPart2.cshtml`?show=true

The test itself looks at the QueryString property of the Request object. If the query string contains an item named show, and if that item is set to true, the if block runs and sets the showMessage variable to true.

There's a trick here, as you can see. Like the name says, the query string is a string. However, you can only test for true and false if the value you're testing is a Boolean (true/false) value. Before you can test the value of the show variable in the query string, you have to convert it to a Boolean value. That's what the AsBool method does — it takes a string as input and converts it to a Boolean value. Clearly, if the string is "true", the AsBool method converts that value to true. If the value of the string is anything else, AsBool returns false.

TIP

Data Types and As() Methods

We've only said so far that when you create a variable, you use the keyword var. That's not the entire story, though. In order to manipulate values — to add numbers, or concatenate strings, or compare dates, or test for true/false — C# has to work with an appropriate internal representation of the value. C# can *usually* figure out what that representation should be (that is, what *type* the data is) based on what you're doing with the values. Now and then, though, it can't do that. If not, you have to help out by explicitly indicating how C# should represent the data. The AsBool method does that — it tells C# that a string value of "true" or "false" should be treated as a Boolean value. Similar methods exist to represent strings as other types as well, like AsInt (treat as an integer), AsDateTime (treat as a date/time), AsFloat (treat as a floating-point number), and so on. When you use these As( ) methods, if C# can't represent the string value as requested, you'll see an error.

In the markup of the page, remove or comment out this element (here it's shown commented out):

```
<!-- <p>@message</p> -->
```

Right where you removed or commented out that text, add the following:

```
@if(showMessage) {
  <p>@message</p>
}
```

The if test says that if the showMessage variable is true, render a <p> element with the value of the message variable.

Summary of your conditional logic

In case you're not entirely sure of what you've just done, here's a summary.

- The message variable is initialized to a default string ("This is the first time ...").
- If the page request is the result of a submit (post), the value of message is changed to "Now you've submitted ..."
- The showMessage variable is initialized to false.
- If the query string contains ?show=true, the showMessage variable is set to true.
- In the markup, if showMessage is true, a <p> element is rendered that shows the value of message. (If showMessage is false, nothing is rendered at that point in the markup.)
- In the markup, if the request is a post, a <p> element is rendered that displays the date and time.

Run the page. There's no message, because showMessage is false, so in the markup the if(showMessage) test returns false.

Click **Submit**. You see the date and time, but still no message.

In your browser, go to the URL box and add the following to the end of the URL: ?show=true and then press Enter.

The page is displayed again. (Because you changed the URL, this is a new request, not a submit.) Click **Submit** again. The message is displayed again, as is the date and time.

In the URL, change ?show=true to ?show=false and press Enter. Submit the page again. The page is back to how you started — no message.

As noted earlier, the logic of this example is a little contrived. However, if is going to come up in many of your pages, and it will take one or more of the forms you've seen here.

Installing a Helper (Displaying a Gravatar Image)

Some tasks that people often want to do on web pages require a lot of code or require extra knowledge. Examples: displaying a chart for data; putting a Facebook "Like" button on a page; sending email from your website; cropping or resizing images; using PayPal for your site. To make it easy to do these kinds of things, ASP.NET Web Pages lets you use *helpers*. Helpers are components that you install for a site and that let you perform typical tasks by using just a few lines of Razor code.

ASP.NET Web Pages has a few helpers built in. However, many helpers are available in packages (add-ins) that are provided using the NuGet package manager. NuGet lets you select a package to install and then it takes care of all the details of the installation.

In this part of the tutorial, you'll install a helper that lets you display a Gravatar ("globally recognized avatar") image. You'll learn two things. One is how to find and install a helper. You'll also learn how a helper makes it easy to do something you'd otherwise need to do by using a lot of code you'd have to write yourself.

You can register your own Gravatar at the Gravatar website at http://www.gravatar.com/, but it is not essential to create a Gravatar account to perform this part of the tutorial.

In WebMatrix, click the **NuGet** button.

This launches the NuGet package manager and displays available packages. (Not all of the packages are helpers; some add functionality to WebMatrix itself, some are additional templates, and so on.) You may get an error message about version incompatibility. You can ignore this error message by clicking **OK** and proceeding with this tutorial.

In the search box, enter "asp.net helpers". NuGet shows the packages that match the search terms.

The ASP.NET Web Helpers Library contains code to simplify many common tasks, including the use of Gravatar

images. Select the **ASP.NET Web Helpers Library** package and then click **Install** to launch the installer. Select **Yes** when asked if you want to install the package, and accept the terms to complete the installation.

That's it. NuGet downloads and installs everything, including any additional components that might be required (*dependencies*).

If for some reason you have to uninstall a helper, the process is very similar. Click the **NuGet** button, click the **Installed** tab, and pick the package you want to uninstall.

Using a Helper in a Page

Now you'll use the helper that you just installed. The process for adding a helper to a page is similar for most helpers.

In WebMatrix, create a page and name it *GravatarTest.cshml*. (You're creating a special page to test the helper, but you can use helpers in any page in your site.)

Inside the <body> element, add a element. Inside the element, type this:

@Gravatar.

The @ character is the same character you've been using to mark Razor code. **Gravatar** is the helper object that you're working with.

As soon as you type the period (.), WebMatrix displays a list of *methods* (functions) that the Gravatar helper makes available:

```
<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title></title>
    </head>
    <body>
        <div>
            @Gravatar.
        </div>
    </body>
</html>
```

Equals
GetHtml
GetUrl
ReferenceEquals

This feature is known as *IntelliSense*. It helps you code by providing context-appropriate choices. IntelliSense works with HTML, CSS, ASP.NET code, JavaScript, and other languages that are supported in WebMatrix. It's another feature that makes it easier to develop web pages in WebMatrix.

Press G on the keyboard, and you see that IntelliSense finds the GetHtml method. Press Tab. IntelliSense inserts the selected method (GetHtml) for you. Type an open parenthesis, and notice that the closing parenthesis is automatically added. Type your email address in quotation marks between the two parenthesis. If you have a Gravatar account, your profile picture will be returned. If you do not have a Gravatar account, a default image is returned. When you're done, the line looks like this:

```
@Gravatar.GetHtml("john@contoso.com")
```

Now view the page in a browser. Either your picture or the default image is displayed, depending on whether you have a Gravatar account.

To get an idea of what the helper is doing for you, view the source of the page in the browser. Along with the HTML that you had in your page, you see an image element that includes an identifier. This is code that the helper rendered into the page at the place where you had @Gravatar.GetHtml. The helper took the information you provided and generated the code that talks directly to Gravatar in order to get back the correct image for supplied account.

The GetHtml method also enables you to customize the image by providing other parameters. The following code shows how to request an image has a width and height of 40 pixels, and uses a specified default image named **wavatar** if the specified account does not exist.

```
@Gravatar.GetHtml("john@contoso.com", 40, "wavatar")
```

This code produces something like the following result (the default image will randomly vary).

Coming Up Next

To keep this tutorial short, we had to focus on only a few basics. Naturally, there's a *lot* more to Razor and C#. You'll learn more as you go through these tutorials. If you're interested in learning more about the programming aspects of Razor and C# right now, you can read a more thorough introduction here: Introduction to ASP.NET Web Programming Using the Razor Syntax.

The next tutorial introduces you to working with a database. In that tutorial, you'll begin creating the sample application that lets you list your favorite movies.

Introducing ASP.NET Web Pages - Displaying Data

2/20/2020 • 18 minutes to read • Edit Online

by Tom FitzMacken

This tutorial shows you how to create a database in WebMatrix and how to display database data in a page when you use ASP.NET Web Pages (Razor). It assumes you have completed the series through Introduction to ASP.NET Web Pages Programming.

What you'll learn:

- How to use WebMatrix tools to create a database and database tables.
- How to use WebMatrix tools to add data to a database.
- How to display data from the database on a page.
- How to run SQL commands in ASP.NET Web Pages.
- How to customize the `WebGrid` helper to change the data display and to add paging and sorting.

Features/technologies discussed:

- WebMatrix database tools.
- `WebGrid` helper.

What You'll Build

In the previous tutorial, you were introduced to ASP.NET Web Pages (*.cshtml* files), to the basics of Razor syntax, and to helpers. In this tutorial, you'll begin creating the actual web application that you'll use for the rest of the series. The app is a simple movie application that lets you view, add, change, and delete information about movies.

When you're done with this tutorial, you'll be able to view a movie listing that looks like this page:

Movies

Title	Genre	Year
When Harry Met Sally	Romantic Comedy	1989
Gone With The Wind	Drama	1939
Ghostbusters	Comedy	1984
Fantasia	Children	1939
Clueless	Comedy	1995
Silverado	Western	1985
The Three Musketeers	Adventure	1973
Ronin	Action	1998

But to begin, you have to create a database.

A Very Brief Introduction to Databases

This tutorial will provide only the briefest introduction to databases. If you have database experience, you can skip this short section.

A database contains one or more tables that contain information — for example, tables for customers, orders, and vendors, or for students, teachers, classes, and grades. Structurally, a database table is like a spreadsheet. Imagine

a typical address book. For each entry in the address book (that is, for each person) you have several pieces of information such as first name, last name, address, email address, and phone number.

ID	FirstName	LastName	Address	Email	Phone
1	Lisa	Miller	4567 Main St	lisa@adatum.com	555-0199
2	Patrick	Hines	123 Elm St	patrickh@tailspintoys.com	555-0111
3	Julia	Ilyina	89 Oak Ave	julia@fourthcoffee.com	555-0166
4	Mark	Alexieff	678 8th St	marka@proseware.com	555-0129
5	Jim	Daly	345 Broad Blvd	jdaly@contoso.com	555-0188

(Rows are sometimes referred to as *records*, and columns are sometimes referred to as *fields*.)

For most database tables, the table has to have a column that contains a unique value, like a customer number, account number, and so on. This value is known as the table's *primary key*, and you use it to identify each row in the table. In the example, the ID column is the primary key for the address book shown in the previous example.

Much of the work you do in web applications consists of reading information out of the database and displaying it on a page. You'll also often gather information from users and add it to a database, or you'll modify records that are already in the database. (We'll cover all of these operations in the course of this tutorial set.)

Database work can be enormously complex and can require specialized knowledge. For this tutorial set, though, you have to understand only basic concepts, which will all be explained as you go.

Creating a Database

WebMatrix includes tools that make it easy to create a database and to create tables in the database. (The structure of a database is referred to as the database's *schema*.) For this tutorial set, you'll create a database that has only one table in it — Movies.

Open WebMatrix if you haven't already done so, and open the WebPagesMovies site that you created in the previous tutorial.

In the left pane, click the **Database** workspace.

The ribbon changes to show database-related tasks. In the ribbon, click **New Database**.

WebMatrix creates a SQL Server CE database (an *.sdf* file) that has the same name as your site — *WebPagesMovies.sdf*. (You won't do this here, but you can rename the file to anything you like, as long as it has an *.sdf* extension.)

Creating a Table

In the ribbon, click **New Table**. WebMatrix opens the table designer in a new tab. (If the New Table option isn't available, make sure that the new database is selected in the tree view on the left.)

In the text box at the top (where the watermark says "Enter table name"), enter "Movies".

The pane underneath the table name is where you define individual columns. For the *Movies* table in this tutorial, you'll create only a few columns: *ID*, *Title*, *Genre*, and *Year*.

In the **Name** box, enter "ID". Entering a value here activates all the controls for the new column.

Tab to the **Data Type** list and choose **int**. This value specifies that the ID column will contain integer (number) data.

> **NOTE**
>
> We won't call it out any more here (much), but you can use standard Windows keyboard gestures to navigate in this grid. For example, you can tab between fields, you can just start typing in order to select an item in a list, and so on.

Tab past the **Default Value** box (that is, leave it blank). Tab to the **Is Primary Key** check box and select it. This option tells the database that the *ID* column will contain the data that identifies individual rows. (That is, each row will have a unique value in the ID column that you can use to find that row.)

Choose the **Is Identity** option. This option tells the database that it should automatically generate the next sequential number for each new row. (The **Is Identity** option works only if you've also selected the **Is Primary Key** option.)

Click in the next grid row, or press Tab twice to finish the current row. Either gesture saves the current row and starts the next one. Notice that the **Default Value** column now says **Null**. (Null is the default value for the default value, so to speak.)

When you've finished defining the new **ID** column, the designer will look like this illustration:

To create the next column, click in the box in the **Name** column. Enter "Title" for the column and then select

nvarchar for the **Data Type** value. The "var" part of **nvarchar** tells the database that the data for this column will be a string whose size might vary from record to record. (The "n" prefix represents "national," which indicates that the field can hold character data for any alphabet or writing system — that is, the field holds Unicode data.)

When you choose **nvarchar**, another box appears where you can enter the maximum length for the field. Enter 50, on the assumption that no movie title that you'll work with in this tutorial will be longer than 50 characters.

Skip **Default Value** and clear the **Allow Nulls** option. You don't want the database to allow any movies to be entered into the database that don't have a title.

When you're done and move to the next row, the designer looks like this illustration:

Repeat these steps to create a column named "Genre", except for the length, set it to just 30.

Create another column named "Year." For the data type, choose **nchar** (not **nvarchar**) and set the length to 4. For the year, you're going to use a 4-digit number like "1995" or "2010", so you don't require a variable-sized column.

Here's what the finished design looks like:

Press Ctrl+S or click the **Save** button in the Quick Access toolbar. Close the database designer by closing the tab.

Adding Some Example Data

Later in this tutorial series you'll create a page where you can enter new movies in a form. For now, however, you can add some example data that you can then display on a page.

In the **Database** workspace in WebMatrix, notice that there's a tree that shows you the *.sdf* file you created earlier. Open the node for your new *.sdf* file, and then open the **Tables** node.

Right-click the **Movies** node and then choose **Data**. WebMatrix opens a grid where you can enter data for the *Movies* table:

Click the **Title** column and enter "When Harry Met Sally". Move to the **Genre** column (you can use the Tab key) and enter "Romantic Comedy". Move to the **Year** column and enter "1989":

Table - (WebPagesMovies.sdf).Movies

ID	Title	Genre	Year
NULL	When Harry Met Sally	Romantic Comedy	1989

Press Enter, and WebMatrix saves the new movie. Notice that the **ID** column has been filled in.

Table - (WebPagesMovies.sdf).Movies

ID	Title	Genre	Year
1	When Harry Met Sally	Romantic Comedy	1989

Enter another movie (for example, "Gone with the Wind", "Drama", "1939"). The ID column is filled in again:

Table - (WebPagesMovies.sdf).Movies

ID	Title	Genre	Year
1	When Harry Met Sally	Romantic Comedy	1989
2	Gone With The Wind	Drama	1939

Enter a third movie (for example, "Ghostbusters", "Comedy"). As an experiment, leave the **Year** column blank and then press Enter. Because you unselected the **Allow Nulls** option, the database shows an error:

Invalid data

Your change could not be committed to the database. After you click OK you can fix the invalid entry or press the Esc key to cancel your changes.

The column cannot contain null values. [Column name = Year,Table name = Movies]

Copy full details to clipboard

OK

Click **OK** to go back and fix the entry (the year for "Ghostbusters" is 1984), and then press Enter.

Fill in several movies until you have 8 or so. (Entering 8 makes it easier to work with paging later. But if that's too many, enter just a few for now.) The actual data doesn't matter.

Table - (WebPagesMovies.sdf).Movies

ID	Title	Genre	Year
1	When Harry Met Sally	Romantic Comedy	1989
2	Gone With The Wind	Drama	1939
4	Ghostbusters	Comedy	1984
5	Fantasia	Children	1939
8	Clueless	Comedy	1995
9	Silverado	Western	1985
10	The Three Musketeers	Adventure	1973
11	Ronin	Action	1998

If you entered all the movies without any errors, the ID values are sequential. If you tried to save an incomplete movie record, the ID numbers might not be sequential. If so, that's okay. The numbers don't have any inherent meaning, and the only thing that's important is that they're unique in the *Movies* table.

Close the tab that contains the database designer.

Now you can turn to displaying this data on a web page.

Displaying Data in a Page by Using the WebGrid Helper

To display data in a page, you're going to use the `WebGrid` helper. This helper produces a display in a grid or table (rows and columns). As you'll see, you'll be able refine the grid with formatting and other features.

To run the grid, you'll have to write a few lines of code. These few lines will serve as a kind of pattern for almost all of the data access that you do in this tutorial.

> **NOTE**
> You actually have many options for displaying data on a page; the `WebGrid` helper is just one. We chose it for this tutorial because it's the easiest way to display data and because it's reasonably flexible. In the next tutorial set, you'll see how to use a more "manual" way to work with data in the page, which gives you more direct control over how to display the data.

In the left pane in WebMatrix, click the **Files** workspace.

The new database you created is in the *App_Data* folder. If the folder didn't already exist, WebMatrix created it for your new database. (The folder might have existed if you'd previously installed helpers.)

In the tree view, select the root of the website. You must select the root of the website; otherwise, the new file might be added to the App_Data folder.

In the ribbon, click **New**. In the **Choose a File Type** box, choose **CSHTML**.

In the **Name** box, name the new page "Movies.cshtml":

Click the **OK** button. WebMatrix opens a new file with some skeleton elements in it. First you'll write some code to go get the data from the database. Then you'll add markup to the page to actually display the data.

Writing the Data Query Code

At the top of the page, between the `@{` and `}` characters, enter the following code. (Make sure that you enter this code between the opening and closing braces.)

```
var db = Database.Open("WebPagesMovies");
var selectedData = db.Query("SELECT * FROM Movies");
var grid = new WebGrid(source: selectedData);
```

The first line opens the database that you created earlier, which is always the first step before doing something with the database. You tell the `Database.Open` method name of the database to open. Notice that you don't include

.sdf in the name. The `Open` method assumes that it's looking for an *.sdf* file (that is, *WebPagesMovies.sdf*) and that the *.sdf* file is in the *App_Data* folder. (Earlier we noted that the *App_Data* folder is reserved; this scenario is one of the places where ASP.NET makes assumptions about that name.)

When the database is opened, a reference to it is put into the variable named `db`. (Which could be named anything.) The `db` variable is how you'll end up interacting with the database.

The second line actually fetches the database data by using the `Query` method. Notice how this code works: the `db` variable has a reference to the opened database, and you invoke the `Query` method by using the `db` variable (`db.Query`).

The query itself is a SQL `Select` statement. (For a little background about SQL, see the explanation later.) In the statement, `Movies` identifies the table to query. The `*` character specifies that the query should return all the columns from the table. (You could also list columns individually, separated by commas.)

The results of the query, if any, are returned and made available in the `selectedData` variable. Again, the variable could be named anything.

Finally, the third line tells ASP.NET that you want to use an instance of the `WebGrid` helper. You create (*instantiate*) the helper object by using the `new` keyword and pass it the query results via the `selectedData` variable. The new `WebGrid` object, along with the results of the database query, are made available in the `grid` variable. You'll need that result in a moment to actually display the data in the page.

At this stage, the database has been opened, you've gotten the data you want, and you've prepared the `WebGrid` helper with that data. Next is to create the markup in the page.

TIP

Structured Query Language (SQL)

SQL is a language that's used in most relational databases for managing data in a database. It includes commands that let you retrieve data and update it, and that let you create, modify, and manage data in database tables. SQL is different than a programming language (like C#). With SQL, you tell the database what you want, and it's the database's job to figure out how to get the data or perform the task. Here are examples of some SQL commands and what they do:

```
Select * From Movies
```

```
SELECT ID, Name, Price FROM Product WHERE Price > 10.00 ORDER BY Name
```

The first `Select` statement gets all the columns (specified by `*`) from the *Movies* table.

The second `Select` statement fetches the ID, Name, and Price columns from records in the *Product* table whose Price column value is more than 10. The command returns the results in alphabetical order based on the values of the Name column. If no records match the price criteria, the command returns an empty set.

```
INSERT INTO Product (Name, Description, Price) VALUES ('Croissant', 'A flaky delight', 1.99)
```

This command inserts a new record into the *Product* table, setting the Name column to "Croissant", the Description column to "A flaky delight", and the price to 1.99.

Notice that when you're specifying a non-numeric value, the value is enclosed in single quotation marks (not double quotation marks, as in C#). You use these quotation marks around text or date values, but not around numbers.

```
DELETE FROM Product WHERE ExpirationDate < '01/01/2008'
```

This command deletes records in the *Product* table whose expiration date column is earlier than January 1, 2008. (The command assumes that the *Product* table has such a column, of course.) The date is entered here in MM/DD/YYYY format, but it should be entered in the format that's used for your locale.

The `Insert` and `Delete` commands don't return result sets. Instead, they return a number that tells you how many records were affected by the command.

For some of these operations (like inserting and deleting records), the process that's requesting the operation has to have appropriate permissions in the database. That's why for production databases you often have to supply a user name and password when you connect to the database.

There are dozens of SQL commands, but they all follow a pattern like the commands you see here. You can use SQL commands to create database tables, count the number of records in a table, calculate prices, and perform many more operations.

Adding Markup to Display the Data

Inside the `<head>` element, set contents of the `<title>` element to "Movies":

```
<head>
    <meta charset="utf-8" />
    <title>Movies</title>
</head>
```

Inside the `<body>` element of the page, add the following:

```
<h1>Movies</h1>
<div>
    @grid.GetHtml()
</div>
```

That's it. The `grid` variable is the value you created when you created the `WebGrid` object in code earlier.

In the WebMatrix tree view, right-click the page and select **Launch in browser**. You'll see something like this page:

Movies

ID	Title	Genre	Year
1	When Harry Met Sally	Romantic Comedy	1989
2	Gone With The Wind	Drama	1939
4	Ghostbusters	Comedy	1984
5	Fantasia	Children	1939
8	Clueless	Comedy	1995
9	Silverado	Western	1985
10	The Three Musketeers	Adventure	1973
11	Ronin	Action	1998

Click a column heading link to sort by that column. Being able to sort by clicking a heading is a feature that's built into the **WebGrid** helper.

The `GetHtml` method, as its name suggests, generates markup that displays the data. By default, the `GetHtml` method generates an HTML `<table>` element. (If you want, you can verify the rendering by looking at the source of the page in the browser.)

Modifying the Look of the Grid

Using the `WebGrid` helper like you just did is easy, but the resulting display is plain. The `WebGrid` helper has all sorts of options that let you control how the data is displayed. There are far too many to explore in this tutorial, but this section will give you an idea of some of those options. A few additional options will be covered in later tutorials in this series.

Specifying Individual Columns to Display

To start, you can specify that you want to display only certain columns. By default, as you've seen, the grid shows all four of the columns from the *Movies* table.

In the *Movies.cshtml* file, replace the `@grid.GetHtml()` markup that you just added with the following:

```
@grid.GetHtml(
    columns: grid.Columns(
        grid.Column("Title"),
        grid.Column("Genre"),
        grid.Column("Year")
    )
)
```

To tell the helper which columns to display, you include a `columns` parameter for the `GetHtml` method and pass in a collection of columns. In the collection, you specify each column to include. You specify an individual column to display by including a `grid.Column` object, and pass in the name of the data column you want. (These columns must be included in the SQL query results — the `WebGrid` helper cannot display columns that were not returned by the query.)

Launch the *Movies.cshtml* page in the browser again, and this time you get a display like the following one (notice that no ID column is displayed):

Movies

Title	Genre	Year
When Harry Met Sally	Romantic Comedy	1989
Gone With The Wind	Drama	1939
Ghostbusters	Comedy	1984
Fantasia	Children	1939
Clueless	Comedy	1995
Silverado	Western	1985
The Three Musketeers	Adventure	1973
Ronin	Action	1998

Changing the Look of the Grid

There are quite a few more options for displaying columns, some of which will be explored in later tutorials in this set. For now, this section will introduce you to ways in which you can style the grid as a whole.

Inside the `<head>` section of the page, just before the closing `</head>` tag, add the following `<style>` element:

```
<style type="text/css">
  .grid { margin: 4px; border-collapse: collapse; width: 600px; }
  .grid th, .grid td { border: 1px solid #C0C0C0; padding: 5px; }
  .head { background-color: #E8E8E8; font-weight: bold; color: #FFF; }
  .alt { background-color: #E8E8E8; color: #000; }
</style>
```

This CSS markup defines classes named `grid`, `head`, and so on. You could also put these style definitions in a separate *.css* file and link that to the page. (In fact, you'll do that later in this tutorial set.) But to make things easy for this tutorial, they're inside the same page that displays the data.

Now you can get the `WebGrid` helper to use these style classes. The helper has a number of properties (for example, `tableStyle`) for just this purpose — you assign a CSS style class name to them, and that class name is rendered as part of the markup that's rendered by the helper.

Change the `grid.GetHtml` markup so that it now looks like this code:

```
@grid.GetHtml(
    tableStyle: "grid",
    headerStyle: "head",
    alternatingRowStyle: "alt",
    columns: grid.Columns(
        grid.Column("Title"),
        grid.Column("Genre"),
        grid.Column("Year")
    )
)
```

What's new here is that you've added `tableStyle`, `headerStyle`, and `alternatingRowStyle` parameters to the `GetHtml` method. These parameters have been set to the names of the CSS styles that you added a moment ago.

Run the page, and this time you see a grid that looks much less plain than before:

Movies

Title	Genre	Year
When Harry Met Sally	Romantic Comedy	1989
Gone With The Wind	Drama	1939
Ghostbusters	Comedy	1984
Fantasia	Children	1939
Clueless	Comedy	1995
Silverado	Western	1985
The Three Musketeers	Adventure	1973
Ronin	Action	1998

To see what the `GetHtml` method generated, you can look at the source of the page in the browser. We won't go into detail here, but the important point is that by specifying parameters like `tableStyle`, you caused the grid to generate HTML tags like the following:

```
<table class="grid">
```

The `<table>` tag has had a `class` attribute added to it that references one of the CSS rules that you added earlier. This code shows you the basic pattern — different parameters for the `GetHtml` method let you reference CSS classes that the method then generates along with the markup. What you do with the CSS classes is up to you.

Adding Paging

As the last task for this tutorial, you'll add paging to the grid. Right now it's no problem to display all your movies at once. But if you added hundreds of movies, the page display would get long.

In the page code, change the line that creates the `WebGrid` object to the following code:

```
var grid = new WebGrid(source: selectedData, rowsPerPage: 3);
```

The only difference from before is that you've added a `rowsPerPage` parameter that's set to 3.

Run the page. The grid displays 3 rows at a time, plus navigation links that let you page through the movies in your database:

Movies

Title	Genre	Year
When Harry Met Sally	Romantic Comedy	1989
Gone With The Wind	Drama	1939
Ghostbusters	Comedy	1984
1 2 3 >		

Coming Up Next

In the next tutorial, you'll learn how to use Razor and C# code to get user input in a form. You'll add a search box to the Movies page so that you can find movies by title or genre.

Complete Listing for Movies Page

```
@{
    var db = Database.Open("WebPagesMovies");
    var selectedData = db.Query("SELECT * FROM Movies");
    var grid = new WebGrid(source: selectedData, rowsPerPage: 3);
}

<!DOCTYPE html>

<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title>Movies</title>
        <style type="text/css">
          .grid { margin: 4px; border-collapse: collapse; width: 600px; }
          .grid th, .grid td { border: 1px solid #C0C0C0; padding: 5px; }
          .head { background-color: #E8E8E8; font-weight: bold; color: #FFF; }
          .alt { background-color: #E8E8E8; color: #000; }
        </style>
    </head>
    <body>
        <h1>Movies</h1>
        <div>
            @grid.GetHtml(
                tableStyle: "grid",
                headerStyle: "head",
                alternatingRowStyle: "alt",
                columns: grid.Columns(
                    grid.Column("Title"),
                    grid.Column("Genre"),
                    grid.Column("Year")
                )
            )
        </div>
    </body>
</html>
```

Introducing ASP.NET Web Pages - HTML Form Basics

2/20/2020 • 25 minutes to read • Edit Online

by Tom FitzMacken

This tutorial shows you the basics of how to create an input form and how to handle the user's input when you use ASP.NET Web Pages (Razor). And now that you've got a database, you'll use your form skills to let users find specific movies in the database. It assumes you have completed the series through Introduction to Displaying Data Using ASP.NET Web Pages.

What you'll learn:

- How to create a form by using standard HTML elements.
- How to read the user's input in a form.
- How to create a SQL query that selectively gets data by using a search term that the user supplies.
- How to have fields in the page "remember" what the user entered.

Features/technologies discussed:

- The `Request` object.
- The SQL `Where` clause.

What You'll Build

In the previous tutorial, you created a database, added data to it, and then used the `WebGrid` helper to display the data. In this tutorial, you'll add a search box that lets you find movies of a specific genre or whose title contains whatever word you enter. (For example, you'll be able to find all movies whose genre is "Action" or whose title contains "Harry" or "Adventure.")

When you're done with this tutorial, you'll have a page like this one:

The listing part of the page is the same as in the last tutorial — a grid. The difference will be that the grid will show only the movies that you searched for.

About HTML Forms

(If you've got experience with creating HTML forms and with the difference between `GET` and `POST`, you can skip this section.)

A form has user input elements — text boxes, buttons, radio buttons, check boxes, drop-down lists, and so on. Users fill in these controls or make selections and then submit the form by clicking a button.

The basic HTML syntax of a form is illustrated by this example:

```
<form method="post">
  <input type="text" name="name" value="" />
  <br/>
  <input type="submit" name="submit" value="Submit" />
</form>
```

When this markup runs in a page, it creates a simple form that looks like this illustration:

The `<form>` element encloses HTML elements to be submitted. (An easy mistake to make is to add elements to the page but then forget to put them inside a `<form>` element. In that case, nothing is submitted.) The `method` attribute tells the browser how to submit the user input. You set this to `post` if you're performing an update on the server or to `get` if you're just fetching data from the server.

TIP

GET, POST, and HTTP Verb Safety

HTTP, the protocol that browsers and servers use to exchange information, is remarkably simple in its basic operations. Browsers use only a few verbs to make requests to servers. When you write code for the web, it's helpful to understand these verbs and how the browser and server use them. Far and away the most commonly used verbs are these:

- `GET`. The browser uses this verb to fetch something from the server. For example, when you type a URL into your browser, the browser performs a `GET` operation to request the page you want. If the page includes graphics, the browser performs additional `GET` operations to get the images. If the `GET` operation has to pass information to the server, the information is passed as part of the URL in the query string.
- `POST`. The browser sends a `POST` request in order to submit data to be added or changed on the server. For example, the `POST` verb is used to create records in a database or change existing ones. Most of the time, when you fill in a form and click the submit button, the browser performs a `POST` operation. In a `POST` operation, the data being passed to the server is in the body of the page.

An important distinction between these verbs is that a `GET` operation is not supposed to change anything on the server — or to put it in a slightly more abstract way, a `GET` operation does not result in a change in state on the server. You can perform a `GET` operation on the same resources as many times as you like, and those resources don't change. (A `GET` operation is often said to be "safe," or to use a technical term, is *idempotent*.) In contrast, of course, a `POST` request changes something on the server each time you perform the operation.

Two examples will help illustrate this distinction. When you perform a search using an engine like Bing or Google, you fill in a form that consists of one text box, and then you click the search button. The browser performs a `GET` operation, with the value you entered into the box passed as part of the URL. Using a `GET` operation for this type of form is fine, because a search operation doesn't change any resources on the server, it just fetches information.

Now consider the process of ordering something online. You fill in the order details and then click the submit button. This operation will be a `POST` request, because the operation will result in changes on the server, such as a new order record, a change in your account information, and perhaps many other changes. Unlike the `GET` operation, you cannot repeat your `POST` request — if you did, each time you resubmitted the request, you'd generate a new order on the server. (In cases like this, websites will often warn you not to click a submit button more than once, or will disable the submit button so that you don't resubmit the form accidentally.)

In the course of this tutorial, you'll use both a `GET` operation and a `POST` operation to work with HTML forms. We'll explain in each case why the verb you use is the appropriate one.

(To learn more about HTTP verbs, see the Method Definitions article on the W3C site.)

Most user input elements are HTML `<input>` elements. They look like `<input type="type" name="name">,` where *type* indicates the kind of user input control you want. These elements are the common ones:

- Text box: `<input type="text">`
- Check box: `<input type="check">`
- Radio button: `<input type="radio">`
- Button: `<input type="button">`
- Submit button: `<input type="submit">`

You can also use the `<textarea>` element to create a multiline text box and the `<select>` element to create a drop-down list or scrollable list. (For more about HTML form elements, see HTML Forms and Input on the W3Schools site.)

The `name` attribute is very important, because the name is how you'll get the value of the element later, as you'll see shortly.

The interesting part is what you, the page developer, do with the user's input. There's no built-in behavior

associated with these elements. Instead, you have to get the values that the user has entered or selected and do something with them. That's what you'll learn in this tutorial.

> **TIP**
>
> **HTML5 and Input Forms**
>
> As you might know, HTML is in transition and the latest version (HTML5) includes support for more intuitive ways for users to enter information. For example, in HTML5, you (the page developer) can tell the page that you want the user to enter a date. The browser can then automatically display a calendar rather than requiring the user to enter a date manually. However, HTML5 is new and is not supported in all browsers yet.
>
> ASP.NET Web Pages supports HTML5 input to the extent that the user's browser does. For an idea of the new attributes for the `<input>` element in HTML5, see HTML <input> type Attribute on the W3Schools site.

Creating the Form

In WebMatrix, in the **Files** workspace, open the *Movies.cshtml* page.

After the closing `</h1>` tag and before the opening `<div>` tag of the `grid.GetHtml` call, add the following markup:

```
<form method="get">
  <div>
    <label for="searchGenre">Genre to look for:</label>
    <input type="text" name="searchGenre" value="" />
    <input type="Submit" value="Search Genre" /><br/>
    (Leave blank to list all movies.)<br/>
    </div>
</form>
```

This markup creates a form that has a text box named `searchGenre` and a submit button. The text box and submit button are enclosed in a `<form>` element whose `method` attribute is set to `get`. (Remember that if you don't put the text box and submit button inside a `<form>` element, nothing will be submitted when you click the button.) You use the `GET` verb here because you're creating a form that does not make any changes on the server — it just results in a search. (In the previous tutorial, you used a `post` method, which is how you submit changes to the server. You'll see that in the next tutorial again.)

Run the page. Although you haven't defined any behavior for the form, you can see what it looks like:

Enter a value into the text box, like "Comedy." Then click **Search Genre**.

Take note of the URL of the page. Because you set the `<form>` element's `method` attribute to `get`, the value you entered is now part of the query string in the URL, like this:

```
http://localhost:45661/Movies.cshtml?searchGenre=Comedy
```

Reading Form Values

The page already contains some code that gets database data and displays the results in a grid. Now you have to add some code that reads the value of the text box so you can run a SQL query that includes the search term.

Because you set the form's method to `get`, you can read the value that was entered into the text box by using code like the following:

```
var searchTerm = Request.QueryString["searchGenre"];
```

The `Request.QueryString` object (the `QueryString` property of the `Request` object) includes the values of elements that were submitted as part of the `GET` operation. The `Request.QueryString` property contains a *collection* (a list) of the values that are submitted in the form. To get any individual value, you specify the name of the element that you want. That's why you have to have a `name` attribute on the `<input>` element (`searchTerm`) that creates the text box. (For more about the `Request` object, see the sidebar later.)

It's simple enough to read the value of the text box. But if the user didn't enter anything at all in the text box but clicked **Search** anyway, you can ignore that click, since there's nothing to search.

The following code is an example that shows how to implement these conditions. (You don't have to add this code yet; you'll do that in a moment.)

```
if(!Request.QueryString["searchGenre"].IsEmpty() ) {
     // Do something here
}
```

The test breaks down in this way:

- Get the value of `Request.QueryString["searchGenre"]`, namely the value that was entered into the `<input>` element named `searchGenre`.
- Find out if it's empty by using the `IsEmpty` method. This method is the standard way to determine whether something (for example, a form element) contains a value. But really, you care only if it's *not* empty, therefore ...
- Add the `!` operator in front of the `IsEmpty` test. (The `!` operator means logical NOT).

In plain English, the entire `if` condition translates into the following: *If the form's searchGenre element is not empty, then ...*

This block sets the stage for creating a query that uses the search term. You'll do that in the next section.

TIP

The Request Object

The `Request` object contains all the information that the browser sends to your application when a page is requested or submitted. This object includes any information that the user provides, like text box values or a file to upload. It also includes all sorts of additional information, like cookies, values in the URL query string (if any), the file path of the page that is running, the type of browser that the user is using, the list of languages that are set in the browser, and much more.

The `Request` object is a *collection* (list) of values. You get an individual value out of the collection by specifying its name:

```
var someValue = Request["name"];
```

The `Request` object actually exposes several subsets. For example:

- `Request.Form` gives you values from elements inside the submitted `<form>` element if the request is a `POST` request.
- `Request.QueryString` gives you just the values in the URL's query string. (In a URL like `http://mysite/myapp/page?searchGenre=action&page=2`, the `?searchGenre=action&page=2` section of the URL is the query string.)
- `Request.Cookies` collection gives you access to cookies that the browser has sent.

To get a value that you know is in the submitted form, you can use `Request["name"]`. Alternatively, you can use the more specific versions `Request.Form["name"]` (for `POST` requests) or `Request.QueryString["name"]` (for `GET` requests). Of course, *name* is the name of the item to get.

The name of the item you want to get has to be unique within the collection you're using. That's why the `Request` object provides the subsets like `Request.Form` and `Request.QueryString`. Suppose that your page contains a form element named `userName` and *also* contains a cookie named `userName`. If you get `Request["userName"]`, it's ambiguous whether you want the form value or the cookie. However, if you get `Request.Form["userName"]` or `Request.Cookie["userName"]`, you're being explicit about which value to get.

It's a good practice to be specific and use the subset of `Request` that you're interested in, like `Request.Form` or `Request.QueryString`. For the simple pages that you're creating in this tutorial, it probably doesn't really make any difference. However, as you create more complex pages, using the explicit version `Request.Form` or `Request.QueryString` can help you avoid problems that can arise when the page contains a form (or multiple forms), cookies, query string values, and so on.

Creating a Query by Using a Search Term

Now that you know how to get the search term that the user entered, you can create a query that uses it. Remember that to get all the movie items out of the database, you're using a SQL query that looks like this statement:

```
SELECT * FROM Movies
```

To get only certain movies, you have to use a query that includes a `Where` clause. This clause lets you set a condition on which rows are returned by the query. Here's an example:

```
SELECT * FROM Movies WHERE Genre = 'Action'
```

The basic format is `WHERE column = value`. You can use different operators besides just `=`, like `>` (greater than), `<` (less than), `<>` (not equal to), `<=` (less than or equal to), etc., depending on what you're looking for.

In case you're wondering, SQL statements are not case sensitive — `SELECT` is the same as `Select` (or even `select`). However, people often capitalize keywords in a SQL statement, like `SELECT` and `WHERE`, to make it easier to read.

Passing the search term as a parameter

Searching for a specific genre is easy enough (`WHERE Genre = 'Action'`), but you want to be able to search for any genre that the user enters. To do that, you create as SQL query that includes a placeholder for the value to search. It will look like this command:

```
SELECT * FROM Movies WHERE Genre = @0
```

The placeholder is the `@` character followed by zero. As you might guess, a query can contain multiple placeholders, and they'd be named `@0`, `@1`, `@2`, etc.

To set up the query and actually pass it the value, you use the code like the following:

```
selectCommand = "SELECT * FROM Movies WHERE Genre = @0";
selectedData = db.Query(selectCommand, Request.QueryString["searchGenre"]);
```

This code is similar to what you've already done to display data in the grid. The only differences are:

- The query contains a placeholder (`WHERE Genre = @0"`).
- The query is put into a variable (`selectCommand`); before, you passed the query directly to the `db.Query` method.
- When you call the `db.Query` method, you pass both the query and the value to use for the placeholder. (If the query had multiple placeholders, you'd pass them all as separate values to the method.)

If you put all these elements together, you get the following code:

```
if(!Request.QueryString["searchGenre"].IsEmpty() ) {
    searchTerm = Request.QueryString["searchGenre"];
    selectCommand = "SELECT * FROM Movies WHERE Genre = @0";
    selectedData = db.Query(selectCommand, searchTerm);
}
```

NOTE

Important! Using placeholders (like `@0`) to pass values to a SQL command is *extremely important* for security. The way you see it here, with placeholders for variable data, is the only way you should construct SQL commands.

Never construct a SQL statement by putting together (concatenating) literal text and values you get from the user. Concatenating user input into a SQL statement opens your site to a *SQL injection attack* where a malicious user submits values to your page that hack your database. (You can read more in the article SQL Injection the MSDN website.)

Updating the Movies Page with Search Code

Now you can update the code in the *Movies.cshtml* file. To begin, replace the code in the code block at the top of the page with this code:

```
var db = Database.Open("WebPagesMovies");
var selectCommand = "SELECT * FROM Movies";
var searchTerm = "";
```

The difference here is that you've put the query into the `selectCommand` variable, which you'll pass to `db.Query` later. Putting the SQL statement into a variable lets you change the statement, which is what you'll do to perform the search.

You've also removed these two lines, which you'll put back in later:

```
var selectedData = db.Query("SELECT * FROM Movies");
var grid = new WebGrid(source: selectedData, rowsPerPage: 3);
```

You don't want to run the query yet (that is, call `db.Query`) and you don't want to initialize the `WebGrid` helper yet either. You'll do those things after you've figured out which SQL statement has to run.

After this rewritten block, you can add the new logic for handling the search. The completed code will look like the following. Update the code in your page so it matches this example:

```
@{
    var db = Database.Open("WebPagesMovies") ;
    var selectCommand = "SELECT * FROM Movies";
    var searchTerm = "";

    if(!Request.QueryString["searchGenre"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Genre = @0";
        searchTerm = Request.QueryString["searchGenre"];
    }

    var selectedData = db.Query(selectCommand, searchTerm);
    var grid = new WebGrid(source: selectedData, defaultSort: "Genre", rowsPerPage:3);
}
```

The page now works like this. Every time the page runs, the code opens the database and the `selectCommand` variable is set to the SQL statement that gets all the records from the `Movies` table. The code also initializes the `searchTerm` variable.

However, if the current request includes a value for the `searchGenre` element, the code sets `selectCommand` to a different query — namely, to one that includes the `Where` clause to search for a genre. It also sets `searchTerm` to whatever was passed for the search box (which might be nothing).

Regardless of which SQL statement is in `selectCommand`, the code then calls `db.Query` to run the query, passing it whatever is in `searchTerm`. If there's nothing in `searchTerm`, it doesn't matter, because in that case there's no parameter to pass the value to `selectCommand` anyway.

Finally, the code initializes the `WebGrid` helper by using the query results, just like before.

You can see that by putting the SQL statement and the search term into variables, you've added flexibility to the code. As you'll see later in this tutorial, you can use this basic framework and keep adding logic for different types of searches.

Testing the Search-by-Genre Feature

In WebMatrix, run the *Movies.cshtml* page. You see the page with the text box for genre.

Enter a genre that you've entered for one of your test records, then click **Search**. This time you see a listing of just the movies that match that genre:

Enter a different genre and search again. Try entering the genre by using all lowercase or all uppercase letters so

that you can see that the search is not case sensitive.

"Remembering" What the User Entered

You might have noticed that after you entered a genre and clicked **Search Genre**, you saw a listing for that genre. However, the search text box was empty — in other words, it didn't remember what you'd entered.

It's important to understand why this behavior occurs. When you submit a page, the browser sends a request to the web server. When ASP.NET gets the request, it creates a brand-new instance of the page, runs the code in it, and then renders the page to the browser again. In effect, though, the page doesn't know that you were just working with a previous version of itself. All it knows is that it got a request that had some form data in it.

Every time you request a page — whether for the first time or by submitting it — you're getting a new page. The web server has no memory of your last request. Neither does ASP.NET, and neither does the browser. The only connection between these separate instances of the page is any data that you transmit between them. If you submit a page, for example, the new page instance can get the form data that was sent by the earlier instance. (Another way to pass data between pages is to use cookies.)

A formal way to describe this situation is to say that web pages are *stateless*. Web servers and the pages themselves and the elements in the page do not maintain any information about the previous state of a page. The web was designed this way because maintaining state for individual requests would quickly exhaust the resources of web servers, which often handle thousands, maybe even hundreds of thousands, of requests per second.

So that's why the text box was empty. After you submitted the page, ASP.NET created a new instance of the page and ran through the code and markup. There was nothing in that code that told ASP.NET to put a value into the text box. So ASP.NET didn't do anything, and the text box was rendered without a value in it.

There's actually an easy way to get around this issue. The genre that you entered into the text box *is* available to you in code — it's in `Request.QueryString["searchGenre"]`.

Update the markup for the text box so that the `value` attribute gets its value from `searchTerm`, like this example:

```
<input type="text" name="searchGenre" value="@Request.QueryString["searchGenre"]" />
```

In this page, you could have also set the `value` attribute to the `searchTerm` variable, since that variable also contains the genre you entered. But using the `Request` object to set the `value` attribute as shown here is the standard way to accomplish this task. (Assuming you even want to do this — in some situations, you might want to render the page *without* values in the fields. It all depends on what's going on with your app.)

> **NOTE**
> You can't "remember" the value of a text box that's used for passwords. It would be a security hole to allow people to fill in a password field by using code.

Run the page again, enter a genre, and click **Search Genre**. This time not only do you see the results of the search, but the text box remembers what you entered last time:

Searching for Any Word in the Title

You can now search for any genre, but you might also want to search for a title. It's hard to get a title exactly right when you search, so instead you can search for a word that appears anywhere inside a title. To do that in SQL, you use the `LIKE` operator and syntax like the following:

```
SELECT * FROM Movies WHERE Title LIKE '%adventure%'
```

This command gets all the movies whose titles contain "adventure". When you use the `LIKE` operator, you include the wildcard character `%` as part of the search term. The search `LIKE 'adventure%'` means "starting with 'adventure'". (Technically, it means "The string 'adventure' followed by anything.") Similarly, the search term `LIKE '%adventure'` means "anything followed by the string 'adventure'", which is another way to say "ending with 'adventure'".

The search term `LIKE '%adventure%'` therefore means "with 'adventure' anywhere in the title." (Technically, "anything in the title, followed by 'adventure', followed by anything.")

Inside the `<form>` element, add the following markup right under the closing `</div>` tag for the genre search (just before the closing `</form>` element):

```
<div>
  <label for="SearchTitle">Movie title contains the following:</label>
  <input type="text" name="searchTitle" value="@Request.QueryString["searchTitle"]" />
  <input type="Submit" value="Search Title" /><br/>
</div>
```

The code to handle this search is similar to the code for the genre search, except that you have to assemble the `LIKE` search. Inside the code block at the top of the page, add this `if` block just after the `if` block for the genre search:

```
if(!Request.QueryString["searchTitle"].IsEmpty() ) {
    selectCommand = "SELECT * FROM Movies WHERE Title LIKE @0";
    searchTerm = "%" + Request["searchTitle"] + "%";
}
```

This code uses the same logic you saw earlier, except that the search uses a `LIKE` operator and the code puts "`%`" before and after the search term.

Notice how it was easy to add another search to the page. All you had to do was:

- Create an `if` block that tested to see whether the relevant search box had a value.
- Set the `selectCommand` variable to a new SQL statement.
- Set the `searchTerm` variable to the value to pass to the query.

Here's the complete code block, which contains the new logic for a title search:

```
@{
    var db = Database.Open("WebPagesMovies") ;
    var selectCommand = "SELECT * FROM Movies";
    var searchTerm = "";

    if(!Request.QueryString["searchGenre"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Genre = @0";
        searchTerm = Request.QueryString["searchGenre"];
    }

   if(!Request.QueryString["searchTitle"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Title LIKE @0";
        searchTerm = "%" + Request["searchTitle"] + "%";
    }

    var selectedData = db.Query(selectCommand, searchTerm);
    var grid = new WebGrid(source: selectedData, defaultSort: "Genre", rowsPerPage:8);
}
```

Here's a summary of what this code does:

- The variables `searchTerm` and `selectCommand` are initialized at the top. You're going to set these variables to the appropriate search term (if any) and appropriate SQL command based on what the user does in the page. The default search is the simple case of getting all the movies from the database.
- In the tests for `searchGenre` and `searchTitle`, the code sets `searchTerm` to the value you want to search for. Those code blocks also set `selectCommand` to an appropriate SQL command for that search.
- The `db.Query` method is invoked only once, using whatever SQL command is in `selectedCommand` and whatever value is in `searchTerm`. If there is no search term (no genre and no title word), the value of `searchTerm` is an empty string. However, that doesn't matter, because in that case the query doesn't require a parameter.

Testing the Title Search Feature

Now you can test your completed search page. Run *Movies.cshtml*.

Enter a genre and click **Search Genre**. The grid displays movies of that genre, like before.

Enter a title word and click **Search Title**. The grid displays movies that have that word in the title.

Leave both text boxes blank and click either button. The grid displays all the movies.

Combining the Queries

You might notice that the searches you can perform are exclusive. You can't search the title and the genre at the same time, even if both search boxes have values in them. For example, you can't search for all action movies whose title contains "Adventure". (As the page is coded now, if you enter values for both genre and title, the title search gets precedence.) To create a search that combines the conditions, you would have to create a SQL query that has syntax like the following:

```
SELECT * FROM Movies WHERE Genre = @0 AND Title LIKE @1
```

And you'd have to run the query by using a statement like the following (roughly speaking):

```
var selectedData = db.Query(selectCommand, searchGenre, searchTitle);
```

Creating logic to allow many permutations of search criteria can get a bit involved, as you can see. Therefore, we'll stop here.

Coming Up Next

In the next tutorial, you'll create a page that uses a form to let users add movies to the database.

Complete Listing for Movie Page (Updated with Search)

```
@{
    var db = Database.Open("WebPagesMovies") ;
    var selectCommand = "SELECT * FROM Movies";
    var searchTerm = "";

    if(!Request.QueryString["searchGenre"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Genre = @0";
        searchTerm = Request.QueryString["searchGenre"];
    }

    if(!Request.QueryString["searchTitle"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Title LIKE @0";
        searchTerm = "%" + Request["searchTitle"] + "%";
    }

    var selectedData = db.Query(selectCommand, searchTerm);
    var grid = new WebGrid(source: selectedData, defaultSort: "Genre", rowsPerPage:3);
}
<!DOCTYPE html>
<html lang="en">
  <head>
    <meta charset="utf-8" />
    <title>Movies</title>
    <style type="text/css">
      .grid { margin: 4px; border-collapse: collapse; width: 600px; }
      .grid th, .grid td { border: 1px solid #C0C0C0; padding: 5px; }
      .head { background-color: #E8E8E8; font-weight: bold; color: #FFF; }
      .alt { background-color: #E8E8E8; color: #000; }
    </style>
  </head>
  <body>
    <h1>Movies</h1>
      <form method="get">
        <div>
        <label for="searchGenre">Genre to look for:</label>
        <input type="text" name="searchGenre" value="@Request.QueryString["searchGenre"]" />
        <input type="Submit" value="Search Genre" /><br/>
        (Leave blank to list all movies.)<br/>
        </div>

        <div>
          <label for="SearchTitle">Movie title contains the following:</label>
          <input type="text" name="searchTitle" value="@Request.QueryString["searchTitle"]" />
          <input type="Submit" value="Search Title" /><br/>
        </div>
      </form>

    <div>
      @grid.GetHtml(
        tableStyle: "grid",
        headerStyle: "head",
        alternatingRowStyle: "alt",
        columns: grid.Columns(
          grid.Column("Title"),
          grid.Column("Genre"),
          grid.Column("Year")
        )
      )
    </div>
  </body>
</html>
```

Introducing ASP.NET Web Pages - Entering Database Data by Using Forms

2/20/2020 • 19 minutes to read • Edit Online

by Tom FitzMacken

This tutorial shows you how to create an entry form and then enter the data that you get from the form into a database table when you use ASP.NET Web Pages (Razor). It assumes you have completed the series through Basics of HTML Forms in ASP.NET Web Pages.

What you'll learn:

- More about how to process entry forms.
- How to add (insert) data in a database.
- How to make sure that users have entered a required value in a form (how to validate user input).
- How to display validation errors.
- How to jump to another page from the current page.

Features/technologies discussed:

- The `Database.Execute` method.
- The SQL `Insert Into` statement
- The `Validation` helper.
- The `Response.Redirect` method.

What You'll Build

In the tutorial earlier that showed you how to create a database, you entered database data by editing the database directly in WebMatrix, working in the **Database** workspace. In most apps, that's not a practical way to put data into the database, though. So in this tutorial, you'll create a web-based interface that lets you or anyone enter data and save it to the database.

You'll create a page where you can enter new movies. The page will contain an entry form that has fields (text boxes) where you can enter a movie title, genre, and year. The page will look like this page:

The text boxes will be HTML `<input>` elements that will look like this markup:

```
<input type="text" name="genre" value="" />
```

Creating the Basic Entry Form

Create a page named *AddMovie.cshtml*.

Replace what's in the file with the following markup. Overwrite everything; you'll add a code block at the top shortly.

```
<!DOCTYPE html>
<html>
<head>
<meta charset="utf-8" />
<title>Add a Movie</title>
</head>
<body>
  <h1>Add a Movie</h1>
  <form method="post">
    <fieldset>
      <legend>Movie Information</legend>
      <p><label for="title">Title:</label>
         <input type="text" name="title" value="@Request.Form["title"]" />
      </p>

      <p><label for="genre">Genre:</label>
         <input type="text" name="genre" value="@Request.Form["genre"]" />
      </p>

      <p><label for="year">Year:</label>
         <input type="text" name="year" value="@Request.Form["year"]" />
      </p>

      <p><input type="submit" name="buttonSubmit" value="Add Movie" /></p>
    </fieldset>
  </form>
</body>
</html>
```

This example shows typical HTML for creating a form. It uses `<input>` elements for the text boxes and for the submit button. The captions for the text boxes are created by using standard `<label>` elements. The `<fieldset>` and `<legend>` elements put a nice box around the form.

Notice that in this page, the `<form>` element uses `post` as the value for the `method` attribute. In the previous tutorial, you created a form that used the `get` method. That was correct, because although the form submitted values to the server, the request did not make any changes. All it did was fetch data in different ways. However, in this page you *will* make changes—you're going to add new database records. Therefore, this form should use the `post` method. (For more about the difference between `GET` and `POST` operations, see theGET, POST, and HTTP Verb Safety sidebar in the previous tutorial.)

Note that each text box has a `name` element (`title`, `genre`, `year`). As you saw in the previous tutorial, these names are important because you must have those names so you can get the user's input later. You can use any names. It's helpful to use meaningful names that help you remember what data you're working with.

The `value` attribute of each `<input>` element contains a bit of Razor code (for example, `Request.Form["title"]`). You learned a version of this trick in the previous tutorial to preserve the value entered into the text box (if any) after the form has been submitted.

Getting the Form Values

Next, you add code that processes the form. In outline, you'll do the following:

1. Check whether the page is being posted (was submitted). You want to your code to run only when users have clicked the button, not when the page first runs.
2. Get the values that the user entered into the text boxes. In this case, because the form is using the `POST` verb,

you get the form values from the `Request.Form` collection.

3. Insert the values as a new record in the *Movies* database table.

At the top of the file, add the following code:

```
@{
    var title = "";
    var genre = "";
    var year = "";

    if(IsPost){
        title = Request.Form["title"];
        genre = Request.Form["genre"];
        year = Request.Form["year"];
    }
}
```

The first few lines create variables (`title`, `genre`, and `year`) to hold the values from the text boxes. The line `if(IsPost)` makes sure that the variables are set *only* when users click the **Add Movie** button — that is, when the form has been posted.

As you saw in an earlier tutorial, you get the value of a text box by using an expression like `Request.Form["name"]`, where *name* is the name of the `<input>` element.

The names of the variables (`title`, `genre`, and `year`) are arbitrary. Like the names that you assign to `<input>` elements, you can call them anything you like. (The names of the variables don't have to match the name attributes of `<input>` elements on the form.) But as with the `<input>` elements, it's a good idea to use variable names that reflect the data that they contain. When you write code, consistent names make it easier for you to remember what data you're working with.

Adding Data to the Database

In the code block you just added, just *inside* the closing brace (`}`) of the `if` block (not just inside the code block), add the following code:

```
var db = Database.Open("WebPagesMovies");
var insertCommand = "INSERT INTO Movies (Title, Genre, Year) VALUES(@0, @1, @2)";
db.Execute(insertCommand, title, genre, year);
```

This example is similar to the code you used in a previous tutorial to fetch and display data. The line that starts with `db =` opens the database, like before, and the next line defines a SQL statement, again as you saw before. However, this time it defines a SQL `Insert Into` statement. The following example shows the general syntax of the `Insert Into` statement:

`INSERT INTO table (column1, column2, column3, ...) VALUES (value1, value2, value3, ...)`

In other words, you specify the table to insert into, then list the columns to insert into, and then list the values to insert. (As noted before, SQL is not case sensitive but some people capitalize the keywords to make it easier to read the command.)

The columns that you're inserting into are already listed in the command — `(Title, Genre, Year)`. The interesting part is how you get the values from the text boxes into the `VALUES` part of the command. Instead of actual values, you see `@0`, `@1`, and `@2`, which are of course placeholders. When you run the command (on the `db.Execute` line), you pass the values that you got from the text boxes.

Important! Remember that the only way you should ever include data entered online by a user in a SQL

statement is to use placeholders, as you see here (`VALUES(@0, @1, @2)`). If you concatenate user input into a SQL statement, you open yourself to a SQL injection attack, as explained in Form Basics in ASP.NET Web Pages (the previous tutorial).

Still inside the `if` block, add the following line after the `db.Execute` line:

```
Response.Redirect("~/Movies");
```

After the new movie has been inserted into the database, this line jumps you (redirects) to the *Movies* page so you can see the movie you just entered. The `~` operator means "root of the website." (The `~` operator works only in ASP.NET pages, not in HTML generally.)

The complete code block looks like this example:

```
@{
    var title = "";
    var genre = "";
    var year = "";

    if(IsPost){
        title = Request.Form["title"];
        genre = Request.Form["genre"];
        year = Request.Form["year"];

        var db = Database.Open("WebPagesMovies");
        var insertCommand = "INSERT INTO Movies (Title, Genre, Year) Values(@0, @1, @2)";
        db.Execute(insertCommand, title, genre, year);
        Response.Redirect("~/Movies");
    }
}
```

Testing the Insert Command (So Far)

You're not done yet, but now is a good time to test.

In the tree view of files in WebMatrix, right-click the *AddMovie.cshtml* page and then click **Launch in browser**.

(If you end up with a different page in the browser, make sure that the URL is `http://localhost:nnnnn/AddMovie`), where *nnnnn* is the port number that you're using.)

Did you get an error page? If so, read it carefully and make sure that the code looks exactly what was listed earlier.

Enter a movie in the form — for example, use "Citizen Kane", "Drama", and "1941". (Or whatever.) Then click **Add Movie**.

If all goes well, you're redirected to the *Movies* page. Make sure that your new movie is listed.

Validating User Input

Go back to the *AddMovie* page, or run it again. Enter another movie, but this time, enter only the title — for example, enter "Singin' in the Rain". Then click **Add Movie**.

You're redirected to the *Movies* page again. You can find the new movie, but it's incomplete.

When you created the *Movies* table, you explicitly said that none of the fields could be null. Here you have an entry form for new movies, and you're leaving fields blank. That's an error.

In this case, the database didn't actually raise (or *throw*) an error. You didn't supply a genre or year, so the code in the *AddMovie* page treated those values as so-called *empty strings*. When the SQL `Insert Into` command ran, the genre and year fields didn't have useful data in them, but they weren't null.

Obviously, you don't want to let users enter half-empty movie information into the database. The solution is to validate the user's input. Initially, the validation will simply make sure that the user has entered a value for all of the fields (that is, that none of them contains an empty string).

TIP

Null and Empty Strings

In programming, there's a distinction between different notions of "no value." In general, a value is *null* if it has never been set or initialized in any way. In contrast, a variable that expects character data (strings) can be set to an *empty string*. In that case, the value is not null; it's just been explicitly set to a string of characters whose length is zero. These two statements show the difference:

```
var firstName;       // Not set, so its value is null
var firstName = "";  // Explicitly set to an empty string -- not null
```

It's a little more complicated than that, but the important point is that `null` represents a sort of undetermined state.

Now and then it's important to understand exactly when a value is null and when it's just an empty string. In the code for the *AddMovie* page, you get the values of the text boxes by using `Request.Form["title"]` and so on. When the page first runs (before you click the button), the value of `Request.Form["title"]` is null. But when you submit the form, `Request.Form["title"]` gets the value of the `title` text box. It's not obvious, but an empty text box is not null; it just has an empty string in it. So when the code runs in response to the button click, `Request.Form["title"]` has an empty string in it.

Why is this distinction important? When you created the *Movies* table, you explicitly said that none of the fields could be null. But here you have an entry form for new movies, and you're leaving fields blank. You would reasonably expect the database to complain when you tried to save new movies that didn't have values for genre or year. But that's the point — even if you leave those text boxes blank, the values aren't null; they're empty strings. As a result, you're able to save new movies to the database with these columns empty — but not null! — values. Therefore, you have to make sure that users don't submit an empty string, which you can do by validating the user's input.

The Validation Helper

ASP.NET Web Pages includes a helper — the `Validation` helper — that you can use to make sure that users enter data that meets your requirements. The `Validation` helper is one of the helpers that's built in to ASP.NET Web Pages, so you don't have to install it as a package by using NuGet, the way you installed the Gravatar helper in an earlier tutorial.

To validate the user's input, you'll do the following:

- Use code to specify that you want to require values in the text boxes on the page.
- Put a test into the code so that the movie information is added to the database only if everything validates properly.
- Add code into the markup to display error messages.

In the code block in the *AddMovie* page, right up at the top before the variable declarations, add the following code:

```
Validation.RequireField("title", "You must enter a title");
Validation.RequireField("genre", "Genre is required");
Validation.RequireField("year", "You haven't entered a year");
```

You call `Validation.RequireField` once for each field (`<input>` element) where you want to require an entry. You can also add a custom error message for each call, like you see here. (We varied the messages just to show that you can put anything you like there.)

If there's a problem, you want to prevent the new movie information from being inserted into the database. In the `if(IsPost)` block, use `&&` (logical AND) to add another condition that tests `Validation.IsValid()`. When you're done, the whole `if(IsPost)` block looks like this code:

```
if(IsPost && Validation.IsValid()){
    title = Request.Form["title"];
    genre = Request.Form["genre"];
    year = Request.Form["year"];

    var db = Database.Open("WebPagesMovies");
    var insertCommand = "INSERT INTO Movies (Title, Genre, Year) Values(@0, @1, @2)";
    db.Execute(insertCommand, title, genre, year);
    Response.Redirect("~/Movies");
}
```

If there's a validation error with any of the fields that you registered by using the `Validation` helper, the `Validation.IsValid` method returns false. And in that case, none of the code in that block will run, so no invalid movie entries will be inserted into the database. And of course you're not redirected to the *Movies* page.

The complete code block, including the validation code, now looks like this example:

```
@{
    Validation.RequireField("title", "You must enter a title");
    Validation.RequireField("genre", "Genre is required");
    Validation.RequireField("year", "You haven't entered a year");

    var title = "";
    var genre = "";
    var year = "";

    if(IsPost && Validation.IsValid()){
       title = Request.Form["title"];
       genre = Request.Form["genre"];
       year = Request.Form["year"];

       var db = Database.Open("WebPagesMovies");
       var insertCommand = "INSERT INTO Movies (Title, Genre, Year) Values(@0, @1, @2)";
       db.Execute(insertCommand, title, genre, year);
       Response.Redirect("~/Movies");
    }
}
```

Displaying Validation Errors

The last step is to display any error messages. You can display individual messages for each validation error, or you can display a summary, or both. For this tutorial, you'll do both so that you can see how it works.

Next to each `<input>` element that you're validating, call the `Html.ValidationMessage` method and pass it the name of the `<input>` element you're validating. You put the `Html.ValidationMessage` method right where you want the error message to appear. When the page runs, the `Html.ValidationMessage` method renders a `<span>` element where the validation error will go. (If there's no error, the `<span>` element is rendered, but there's no text in it.)

Change the markup in the page so that it includes an `Html.ValidationMessage` method for each of the three `<input>` elements on the page, like this example:

```
<p><label for="title">Title:</label>
     <input type="text" name="title" value="@Request.Form["title"]" />
      @Html.ValidationMessage("title")
  </p>

  <p><label for="genre">Genre:</label>
     <input type="text" name="genre" value="@Request.Form["genre"]" />
      @Html.ValidationMessage("genre")
  </p>

  <p><label for="year">Year:</label>
     <input type="text" name="year" value="@Request.Form["year"]" />
      @Html.ValidationMessage("year")
  </p>
```

To see how the summary works, also add the following markup and code right after the `<h1>Add a Movie</h1>` element on the page:

```
@Html.ValidationSummary()
```

By default, the `Html.ValidationSummary` method displays all the validation messages in a list (a `<ul>` element that's inside a `<div>` element). As with the `Html.ValidationMessage` method, the markup for the validation summary is always rendered; if there are no errors, no list items are rendered.

The summary can be an alternative way to display validation messages instead of by using the `Html.ValidationMessage` method to display each field-specific error. Or you can use both a summary and the details. Or you can use the `Html.ValidationSummary` method to display a generic error and then use individual `Html.ValidationMessage` calls to display details.

The complete page now looks like this example:

```
@{
    Validation.RequireField("title", "You must enter a title");
    Validation.RequireField("genre", "Genre is required");
    Validation.RequireField("year", "You haven't entered a year");

    var title = "";
    var genre = "";
    var year = "";

    if(IsPost && Validation.IsValid()){
       title = Request.Form["title"];
       genre = Request.Form["genre"];
       year = Request.Form["year"];

       var db = Database.Open("WebPagesMovies");
       var insertCommand = "INSERT INTO Movies (Title, Genre, Year) Values(@0, @1, @2)";
       db.Execute(insertCommand, title, genre, year);
       Response.Redirect("~/Movies");
    }
}

<!DOCTYPE html>
<html>
<head>
  <meta charset="utf-8" />
  <title>Add a Movie</title>
</head>
<body>
  <h1>Add a Movie</h1>
  @Html.ValidationSummary()
  <form method="post">
    <fieldset>
      <legend>Movie Information</legend>
      <p><label for="title">Title:</label>
         <input type="text" name="title" value="@Request.Form["title"]" />
          @Html.ValidationMessage("title")
      </p>

      <p><label for="genre">Genre:</label>
         <input type="text" name="genre" value="@Request.Form["genre"]" />
          @Html.ValidationMessage("genre")
      </p>

      <p><label for="year">Year:</label>
         <input type="text" name="year" value="@Request.Form["year"]" />
          @Html.ValidationMessage("year")
      </p>

      <p><input type="submit" name="buttonSubmit" value="Add Movie" /></p>
    </fieldset>
  </form>
</body>
</html>
```

That's it. You can now test the page by adding a movie but leaving out one or more of the fields. When you do, you see the following error display:

Styling the Validation Error Messages

You can see that there are error messages, but they don't really stand out very well. There's an easy way to style the error messages, though.

To style the individual error messages that are displayed by `Html.ValidationMessage`, create a CSS style class named `field-validation-error`. To define the look for the validation summary, create a CSS style class named `validation-summary-errors`.

To see how this technique works, add a `<style>` element inside the `<head>` section of the page. Then define style classes named `field-validation-error` and `validation-summary-errors` that contain the following rules:

```
<head>
  <meta charset="utf-8" />
  <title>Add a Movie</title>
  <style type="text/css">
    .field-validation-error {
      font-weight:bold;
      color:red;
      background-color:yellow;
     }
    .validation-summary-errors{
      border:2px dashed red;
      color:red;
      background-color:yellow;
      font-weight:bold;
      margin:12px;
    }
  </style>
</head>
```

Normally you'd probably put style information into a separate *.css* file, but for simplicity you can put them in the page for now. (Later in this tutorial set, you'll move the CSS rules to a separate *.css* file.)

If there's a validation error, the `Html.ValidationMessage` method renders a `<span>` element that includes `class="field-validation-error"`. By adding a style definition for that class, you can configure what the message looks like. If there are errors, the `ValidationSummary` method likewise dynamically renders the attribute `class="validation-summary-errors"`.

Run the page again and deliberately leave out a couple of the fields. The errors are now more noticeable. (In fact, they're overdone, but that's just to show what you can do.)

Adding a Link to the Movies Page

One final step is to make it convenient to get to the *AddMovie* page from the original movie listing.

Open the *Movies* page again. After the closing `</div>` tag that follows the `WebGrid` helper, add the following markup:

```
<p>
  <a href="~/AddMovie">Add a movie</a>
</p>
```

As you saw before, ASP.NET interprets the `~` operator as the root of the website. You don't have to use the `~` operator; you could use the markup `<a href="./AddMovie">Add a movie</a>` or some other way to define the path that HTML understands. But the `~` operator is a good general approach when you create links for Razor pages, because it makes the site more flexible — if you move the current page to a subfolder, the link will still go to the *AddMovie* page. (Remember that the `~` operator only works in *.cshtml* pages. ASP.NET understands it, but it's not standard HTML.)

When you're done, run the *Movies* page. It will look like this page:

Click the **Add a movie** link to make sure that it goes to the *AddMovie* page.

Coming Up Next

In the next tutorial, you'll learn how to let users edit data that's already in the database.

Complete Listing for AddMovie Page

```
@{
    Validation.RequireField("title", "You must enter a title");
```

```
    Validation.RequireField("title", "You must enter a title");
    Validation.RequireField("genre", "Genre is required");
    Validation.RequireField("year", "You haven't entered a year");

    var title = "";
    var genre = "";
    var year = "";

    if(IsPost && Validation.IsValid()){
       title = Request.Form["title"];
       genre = Request.Form["genre"];
       year = Request.Form["year"];

       var db = Database.Open("WebPagesMovies");
       var insertCommand = "INSERT INTO Movies (Title, Genre, Year) Values(@0, @1, @2)";
       db.Execute(insertCommand, title, genre, year);
       Response.Redirect("~/Movies");
    }
}

<!DOCTYPE html>
<html>
<head>
<meta charset="utf-8" />
<title>Add a Movie</title>
      <style type="text/css">
    .field-validation-error {
      font-weight:bold;
      color:red;
      background-color:yellow;
     }
    .validation-summary-errors{
      border:2px dashed red;
      color:red;
      background-color:yellow;
      font-weight:bold;
      margin:12px;
    }
  </style>
</head>
<body>
  <h1>Add a Movie</h1>
  @Html.ValidationSummary()
  <form method="post">
    <fieldset>
      <legend>Movie Information</legend>
      <p><label for="title">Title:</label>
         <input type="text" name="title" value="@Request.Form["title"]" />
          @Html.ValidationMessage("title")
      </p>

      <p><label for="genre">Genre:</label>
         <input type="text" name="genre" value="@Request.Form["genre"]" />
         @Html.ValidationMessage("genre")
      </p>

      <p><label for="year">Year:</label>
         <input type="text" name="year" value="@Request.Form["year"]" />
          @Html.ValidationMessage("year")
      </p>

      <p><input type="submit" name="buttonSubmit" value="Add Movie" /></p>
    </fieldset>
  </form>
</body>
</html>
```

Introducing ASP.NET Web Pages - Updating Database Data

2/20/2020 • 21 minutes to read • Edit Online

by Tom FitzMacken

This tutorial shows you how to update (change) an existing database entry when you use ASP.NET Web Pages (Razor). It assumes you have completed the series through Entering Data by Using Forms Using ASP.NET Web Pages.

What you'll learn:

- How to select an individual record in the `WebGrid` helper.
- How to read a single record from a database.
- How to preload a form with values from the database record.
- How to update an existing record in a database.
- How to store information in the page without displaying it.
- How to use a hidden field to store information.

Features/technologies discussed:

- The `WebGrid` helper.
- The SQL `Update` command.
- The `Database.Execute` method.
- Hidden fields (`<input type="hidden">`).

What You'll Build

In the previous tutorial, you learned how to add a record to a database. Here, you'll learn how to display a record for editing. In the *Movies* page, you'll update the `WebGrid` helper so that it displays an **Edit** link next to each movie:

When you click the **Edit** link, it takes you to a different page, where the movie information is already in a form:

You can change any of the values. When you submit the changes, the code in the page updates the database and takes you back to the movie listing.

This part of the process works almost exactly like the *AddMovie.cshtml* page you created in the previous tutorial, so much of this tutorial will be familiar.

There are several ways you could implement a way to edit an individual movie. The approach shown was chosen because it's easy to implement and easy to understand.

Adding an Edit Link to the Movie Listing

To begin, you'll update the *Movies* page so that each movie listing also contains an **Edit** link.

Open the *Movies.cshtml* file.

In the body of the page, change the `WebGrid` markup by adding a column. Here's the modified markup:

```
@grid.GetHtml(
    tableStyle: "grid",
    headerStyle: "head",
    alternatingRowStyle: "alt",
    columns: grid.Columns(
        grid.Column(format: @<a href="~/EditMovie?id=@item.ID">Edit</a>),
        grid.Column("Title"),
        grid.Column("Genre"),
        grid.Column("Year")
    )
)
```

The new column is this one:

```
grid.Column(format: @<a href="~/EditMovie?id=@item.ID)">Edit</a>)
```

The point of this column is to show a link (`<a>` element) whose text says "Edit". What we're after is to create a link that looks like the following when the page runs, with the `id` value different for each movie:

```
http://localhost:43097/EditMovie?id=7
```

This link will invoke a page named *EditMovie*, and it will pass the query string `?id=7` to that page.

The syntax for the new column might look a bit complex, but that's only because it puts together several elements. Each individual element is straightforward. If you concentrate on just the `<a>` element, you see this markup:

```
<a href="~/EditMovie?id=@item.ID)">Edit</a>
```

Some background about how the grid works: the grid displays rows, one for each database record, and it displays

columns for each field in the database record. While each grid row is being constructed, the `item` object contains the database record (item) for that row. This arrangement gives you a way in code to get at the data for that row. That's what you see here: the expression `item.ID` is getting the ID value of the current database item. You could get any of the database values (title, genre, or year) the same way by using `item.Title`, `item.Genre`, or `item.Year`.

The expression `"~/EditMovie?id=@item.ID` combines the hard-coded part of the target URL (`~/EditMovie?id=`) with this dynamically derived ID. (You saw the `~` operator in the previous tutorial; it's an ASP.NET operator that represents the current website root.)

The result is that this part of the markup in the column simply produces something like the following markup at run time:

```
href="/EditMovie?id=2"
```

Naturally, the actual value of `id` will be different for each row.

Creating a Custom Display for a Grid Column

Now back to the grid column. The three columns you originally had in the grid displayed only data values (title, genre, and year). You specified this display by passing the name of the database column — for example, `grid.Column("Title")`.

This new **Edit** link column is different. Instead of specifying a column name, you're passing a `format` parameter. This parameter lets you define markup that the `WebGrid` helper will render along with the `item` value to display the column data as bold or green or in whatever format that you want. For example, if you wanted the title to appear bold, you could create a column like this example:

```
grid.Column(format:@<strong>@item.Title</strong>)
```

(The various `@` characters you see in the `format` property mark the transition between markup and a code value.)

Once you know about the `format` property, it's easier to understand how the new **Edit** link column is put together:

```
grid.Column(format: @<a href="~/EditMovie?id=@item.ID">Edit</a>),
```

The column consists *only* of the markup that renders the link, plus some information (the ID) that's extracted from the database record for the row.

TIP

Named Parameters and Positional Parameters for a Method

Many times when you've called a method and passed parameters to it, you've simply listed the parameter values separated by commas. Here are a couple of examples:

`db.Execute(insertCommand, title, genre, year)`

`Validation.RequireField("title", "You must enter a title")`

We didn't mention the issue when you first saw this code, but in each case, you're passing parameters to the methods in a specific order — namely, the order in which the parameters are defined in that method. For `db.Execute` and `Validation.RequireFields`, if you mixed up the order of the values you pass, you'd get an error message when the page runs, or at least some strange results. Clearly, you have to know the order to pass the parameters in. (In WebMatrix, IntelliSense can help you learn figure out the name, type, and order of the parameters.)

As an alternative to passing values in order, you can use *named parameters*. (Passing parameters in order is known as using *positional parameters*.) For named parameters, you explicitly include the name of the parameter when passing its value. You've used named parameters already a number of times in these tutorials. For example:

```
var grid = new WebGrid(source: selectedData, defaultSort: "Genre", rowsPerPage:3)
```

and

```
@grid.GetHtml(
    tableStyle: "grid",
    headerStyle: "head",
    alternatingRowStyle: "alt",
    columns: grid.Columns(
       grid.Column("Title"),
       grid.Column("Genre"),
       grid.Column("Year")
    )
)
```

Named parameters are handy for a couple of situations, especially when a method takes many parameters. One is when you want to pass only one or two parameters, but the values you want to pass are not among the first positions in the parameter list. Another situation is when you want to make your code more readable by passing the parameters in the order that makes the most sense to you.

Obviously, to use named parameters, you have to know the names of the parameters. WebMatrix IntelliSense can *show* you the names, but it cannot currently fill them in for you.

Creating the Edit Page

Now you can create the *EditMovie* page. When users click the **Edit** link, they'll end up on this page.

Create a page named *EditMovie.cshtml* and replace what's in the file with the following markup:

```
<!DOCTYPE html>
<html>
  <head>
   <meta charset="utf-8" />
   <title>Edit a Movie</title>
    <style>
      .validation-summary-errors{
        border:2px dashed red;
        color:red;
        font-weight:bold;
        margin:12px;
      }
    </style>
  </head>
  <body>
    <h1>Edit a Movie</h1>
    @Html.ValidationSummary()
    <form method="post">
      <fieldset>
        <legend>Movie Information</legend>

        <p><label for="title">Title:</label>
           <input type="text" name="title" value="@title" /></p>

        <p><label for="genre">Genre:</label>
           <input type="text" name="genre" value="@genre" /></p>

        <p><label for="year">Year:</label>
           <input type="text" name="year" value="@year" /></p>

        <input type="hidden" name="movieid" value="@movieId" />

        <p><input type="submit" name="buttonSubmit" value="Submit Changes" /></p>
      </fieldset>
    </form>
  </body>
</html>
```

This markup and code is similar to what you have in the *AddMovie* page. There's a small difference in the text for the submit button. As with the *AddMovie* page, there's an `Html.ValidationSummary` call that will display validation errors if there are any. This time we're leaving out calls to `Validation.Message`, since errors will be displayed in the validation summary. As noted in the previous tutorial, you can use the validation summary and the individual error messages in various combinations.

Notice again that the `method` attribute of the `<form>` element is set to `post`. As with the *AddMovie.cshtml* page, this page makes changes to the database. Therefore, this form should perform a `POST` operation. (For more about the difference between `GET` and `POST` operations, see the GET, POST, and HTTP Verb Safety sidebar in the tutorial on HTML forms.)

As you saw in an earlier tutorial, the `value` attributes of the text boxes are being set with Razor code in order to preload them. This time, though, you're using variables like `title` and `genre` for that task instead of `Request.Form["title"]`:

```
<input type="text" name="title" value="@title" />
```

As before, this markup will preload the text box values with the movie values. You'll see in a moment why it's handy to use variables this time instead of using the `Request` object.

There's also a `<input type="hidden">` element on this page. This element stores the movie ID without making it visible on the page. The ID is initially passed to the page by using a query string value (`?id=7` or similar in the URL). By putting the ID value into a hidden field, you can make sure that it's available when the form is submitted,

even if you no longer have access to the original URL that the page was invoked with.

Unlike the *AddMovie* page, the code for the *EditMovie* page has two distinct functions. The first function is that when the page is displayed for the first time (and *only* then), the code gets the movie ID from the query string. The code then uses the ID to read the corresponding movie out of the database and display (preload) it in the text boxes.

The second function is that when the user clicks the **Submit Changes** button, the code has to read the values of the text boxes and validate them. The code also has to update the database item with the new values. This technique is similar to adding a record, as you saw in *AddMovie*.

Adding Code to Read a Single Movie

To perform the first function, add this code to the top of the page:

```
@{
    var title = "";
    var genre = "";
    var year = "";
    var movieId = "";

    if(!IsPost){
        if(!Request.QueryString["ID"].IsEmpty()){
            movieId = Request.QueryString["ID"];
            var db = Database.Open("WebPagesMovies");
            var dbCommand = "SELECT * FROM Movies WHERE ID = @0";
            var row = db.QuerySingle(dbCommand, movieId);
            title = row.Title;
            genre = row.Genre;
            year = row.Year;
        }
        else{
            Validation.AddFormError("No movie was selected.");
        }
    }
}
```

Most of this code is inside a block that starts `if(!IsPost)`. The `!` operator means "not," so the expression means *if this request is not a post submission*, which is an indirect way of saying *if this request is the first time that this page has been run*. As noted earlier, this code should run *only* the first time the page runs. If you didn't enclose the code in `if(!IsPost)`, it would run every time the page is invoked, whether the first time or in response to a button click.

Notice that the code includes an `else` block this time. As we said when we introduced `if` blocks, sometimes you want to run alternative code if the condition you're testing isn't true. That's the case here. If the condition passes (that is, if the ID passed to the page is ok), you read a row from the database. However, if the condition doesn't pass, the `else` block runs and the code sets an error message.

Validating a Value Passed to the Page

The code uses `Request.QueryString["id"]` to get the ID that's passed to the page. The code makes sure that a value was actually passed for the ID. If no value was passed, the code sets a validation error.

This code shows a different way to validate information. In the previous tutorial, you worked with the `Validation` helper. You registered fields to validate, and ASP.NET automatically did the validation and displayed errors by using `Html.ValidationMessage` and `Html.ValidationSummary`. In this case, however, you're not really validating user input. Instead, you're validating a value that was passed to the page from elsewhere. The `Validation` helper doesn't do that for you.

Therefore, you check the value yourself, by testing it with `if(!Request.QueryString["ID"].IsEmpty()`). If there's a problem, you can display the error by using `Html.ValidationSummary`, as you did with the `Validation` helper. To do that, you call `Validation.AddFormError` and pass it a message to display. `Validation.AddFormError` is a built-in method that lets you define custom messages that tie in with the validation system you're already familiar with. (Later in this tutorial we'll talk about how to make this validation process a little more robust.)

After making sure that there's an ID for the movie, the code reads the database, looking for only a single database item. (You probably have noticed the general pattern for database operations: open the database, define a SQL statement, and run the statement.) This time, the SQL `Select` statement includes `WHERE ID = @0`. Because the ID is unique, only one record can be returned.

The query is performed by using `db.QuerySingle` (not `db.Query`, as you used for the movie listing), and the code puts the result into the `row` variable. The name `row` is arbitrary; you can name the variables anything you like. The variables initialized at the top are then filled with the movie details so that these values can be displayed in the text boxes.

Testing the Edit Page (So Far)

If you'd like to test your page, run the *Movies* page now and click an **Edit** link next to any movie. You'll see the *EditMovie* page with the details filled in for the movie you selected:

Notice that the URL of the page includes something like `?id=10` (or some other number). So far you've tested that **Edit** links in the *Movie* page work, that your page is reading the ID from the query string, and that the database query to get a single movie record is working.

You can change the movie information, but nothing happens when you click **Submit Changes**.

Adding Code to Update the Movie with the User's Changes

In the *EditMovie.cshtml* file, to implement the second function (saving changes), add the following code just inside the closing brace of the `@` block. (If you're not sure exactly where to put the code, you can look at the complete code listing for the Edit Movie page that appears at the end of this tutorial.)

```
if(IsPost){
    Validation.RequireField("title", "You must enter a title");
    Validation.RequireField("genre", "Genre is required");
    Validation.RequireField("year", "You haven't entered a year");
    Validation.RequireField("movieid", "No movie ID was submitted!");

    title = Request.Form["title"];
    genre = Request.Form["genre"];
    year = Request.Form["year"];
    movieId = Request.Form["movieId"];

    if(Validation.IsValid()){
        var db = Database.Open("WebPagesMovies");
        var updateCommand = "UPDATE Movies SET Title=@0, Genre=@1, Year=@2 WHERE Id=@3";
        db.Execute(updateCommand, title, genre, year, movieId);
        Response.Redirect("~/Movies");
   }
}
```

Again, this markup and code is similar to the code in *AddMovie*. The code is in an `if(IsPost)` block, because this code runs only when the user clicks the **Submit Changes** button — that is, when (and only when) the form has been posted. In this case, you're not using a test like `if(IsPost && Validation.IsValid())` — that is, you're not combining both tests by using AND. In this page, you first determine whether there's a form submission (`if(IsPost)`), and only then register the fields for validation. Then you can test the validation results (`if(Validation.IsValid()`). The flow is slightly different than in the *AddMovie.cshtml* page, but the effect is the same.

You get the values of the text boxes by using `Request.Form["title"]` and similar code for the other `<input>` elements. Notice that this time, the code gets the movie ID out of the hidden field (`<input type="hidden">`). When the page ran the first time, the code got the ID out of the query string. You get the value from the hidden field to make sure that you're getting the ID of the movie that was originally displayed, in case the query string was somehow altered since then.

The really important difference between the *AddMovie* code and this code is that in this code you use the SQL `Update` statement instead of the `Insert Into` statement. The following example shows the syntax of the SQL `Update` statement:

```
UPDATE table SET col1="value", col2="value", col3="value" ... WHERE ID = value
```

You can specify any columns in any order, and you don't necessarily have to update every column during an `Update` operation. (You cannot update the ID itself, because that would in effect save the record as a new record, and that's not allowed for an `Update` operation.)

> **NOTE**
>
> **Important** The `Where` clause with the ID is very important, because that's how the database knows which database record you want to update. If you left off the `Where` clause, the database would update *every* record in the database. In most cases, that would be a disaster.

In the code, the values to update are passed to the SQL statement by using placeholders. To repeat what we've said before: for security reasons, *only* use placeholders to pass values to a SQL statement.

After the code uses `db.Execute` to run the `Update` statement, it redirects back to the listing page, where you can see the changes.

TIP

Different SQL Statements, Different Methods

You might have noticed that you use slightly different methods to run different SQL statements. To run a `Select` query that potentially returns multiple records, you use the `Query` method. To run a `Select` query that you know will return only one database item, you use the `QuerySingle` method. To run commands that make changes but that don't return database items, you use the `Execute` method.

You have to have different methods because each of them returns different results, as you saw already in the difference between `Query` and `QuerySingle`. (The `Execute` method actually returns a value also — namely, the number of database rows that were affected by the command — but you've been ignoring that so far.)

Of course, the `Query` method might return only one database row. However, ASP.NET always treats the results of the `Query` method as a collection. Even if the method returns just one row, you have to extract that single row from the collection. Therefore, in situations where you *know* you'll get back only one row, it's a bit more convenient to use `QuerySingle`.

There are a few other methods that perform specific types of database operations. You can find a listing of database methods in the ASP.NET Web Pages API Quick Reference.

Making Validation for the ID More Robust

The first time that the page runs, you get the movie ID from the query string so that you can go get that movie from the database. You made sure that there actually was a value to go look for, which you did by using this code:

```
if(!IsPost){
    if(!Request.QueryString["ID"].IsEmpty()){
        // Etc.
    }
}
```

You used this code to make sure that if a user gets to the *EditMovies* page without first selecting a movie in the *Movies* page, the page would display a user-friendly error message. (Otherwise, users would see an error that would probably just confuse them.)

However, this validation isn't very robust. The page might also be invoked with these errors:

- The ID isn't a number. For example, the page could be invoked with a URL like `http://localhost:nnnnn/EditMovie?id=abc`.
- The ID is a number, but it references a movie that doesn't exist (for example, `http://localhost:nnnnn/EditMovie?id=100934`).

If you're curious to see the errors that result from these URLs, run the *Movies* page. Select a movie to edit, and then change the URL of the *EditMovie* page to a URL that contains an alphabetic ID or the ID of a non-existent movie.

So what should you do? The first fix is to make sure that not only is an ID passed to the page, but that the ID is an integer. Change the code for the `!IsPost` test to look like this example:

```
if(!IsPost){
    if(!Request.QueryString["ID"].IsEmpty() && Request.QueryString["ID"].IsInt()) {
       // Etc.
```

You've added a second condition to the `IsEmpty` test, linked with `&&` (logical AND):

```
Request.QueryString["ID"].IsInt()
```

You might remember from the Introduction to ASP.NET Web Pages Programming tutorial that methods like `AsBool` an `AsInt` convert a character string to some other data type. The `IsInt` method (and others, like `IsBool` and `IsDateTime`) are similar. However, they test only whether you *can* convert the string, without actually performing the conversion. So here you're essentially saying *If the query string value can be converted to an integer ....*

The other potential problem is looking for a movie that doesn't exist. The code to get a movie looks like this code:

```
var row = db.QuerySingle(dbCommand, movieId);
```

If you pass a `movieId` value to the `QuerySingle` method that doesn't correspond to an actual movie, nothing is returned and the statements that follow (for example, `title=row.Title`) result in errors.

Again there's an easy fix. If the `db.QuerySingle` method returns no results, the `row` variable will be null. So you can check whether the `row` variable is null before you try to get values from it. The following code adds an `if` block around the statements that get the values out of the `row` object:

```
if(row != null) {
    title = row.Title;
    genre = row.Genre;
    year = row.Year;
}
else{
    Validation.AddFormError("No movie was found for that ID.");
}
```

With these two additional validation tests, the page becomes more bullet-proof. The complete code for the `!IsPost` branch now looks like this example:

```
if(!IsPost){
    if(!Request.QueryString["ID"].IsEmpty() && Request.QueryString["ID"].IsInt()) {
        movieId = Request.QueryString["ID"];
        var db = Database.Open("WebPagesMovies");
        var dbCommand = "SELECT * FROM Movies WHERE ID = @0";
        var row = db.QuerySingle(dbCommand, movieId);

        if(row != null) {
            title = row.Title;
            genre = row.Genre;
            year = row.Year;
        }
        else {
            Validation.AddFormError("No movie was found for that ID.");
        }
    }
    else {
        Validation.AddFormError("No movie was selected.");
    }
}
```

We'll note once more that this task is a good use for an `else` block. If the tests don't pass, the `else` blocks set error messages.

Adding a Link to Return to the Movies Page

A final and helpful detail is to add a link back to the *Movies* page. In the ordinary flow of events, users will start at the *Movies* page and click an **Edit** link. That brings them to the *EditMovie* page, where they can edit the movie and click the button. After the code processes the change, it redirects back to the *Movies* page.

However:

- The user might decide not to change anything.
- The user might have gotten to this page without first clicking an **Edit** link in the *Movies* page.

Either way, you want to make it easy for them to return to the main listing. It's an easy fix — add the following markup just after the closing `</form>` tag in the markup:

```
<p><a href="~/Movies">Return to movie listing</a></p>
```

This markup uses the same syntax for an `<a>` element that you've seen elsewhere. The URL includes `~` to mean "root of the website."

Testing the Movie Update Process

Now you can test. Run the *Movies* page, and click **Edit** next to a movie. When the *EditMovie* page appears, make changes to the movie and click **Submit Changes**. When the movie listing appears, make sure that your changes are shown.

To make sure that validation is working, click **Edit** for another movie. When you get to the *EditMovie* page, clear the **Genre** field (or **Year** field, or both) and try to submit your changes. You'll see an error, as you'd expect:

Click the **Return to movie listing** link to abandon your changes and return to the *Movies* page.

Coming Up Next

In the next tutorial, you'll see how to delete a movie record.

Complete Listing for Movie Page (Updated with Edit Links)

```
@{
    var db = Database.Open("WebPagesMovies") ;
    var selectCommand = "SELECT * FROM Movies";
    var searchTerm = "";

    if(!Request.QueryString["searchGenre"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Genre = @0";
        searchTerm = Request.QueryString["searchGenre"];
    }

    if(!Request.QueryString["searchTitle"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Title LIKE @0";
        searchTerm = "%" + Request.QueryString["searchTitle"] + "%";
    }

    var selectedData = db.Query(selectCommand, searchTerm);
    var grid = new WebGrid(source: selectedData, defaultSort: "Genre", rowsPerPage:3);

Introducing ASP.NET Web Pages - Deleting Database Data

2/20/2020 • 12 minutes to read • Edit Online

by Tom FitzMacken

This tutorial shows you how to delete an individual database entry. It assumes you have completed the series through Updating Database Data in ASP.NET Web Pages.

What you'll learn:

- How to select an individual record from a listing of records.
- How to delete a single record from a database.
- How to check that a specific button was clicked in a form.

Features/technologies discussed:

- The `WebGrid` helper.
- The SQL `Delete` command.
- The `Database.Execute` method to run a SQL `Delete` command.

What You'll Build

In the previous tutorial, you learned how to update an existing database record. This tutorial is similar, except that instead of updating the record, you'll delete it. The processes are much the same, except that deleting is simpler, so this tutorial will be short.

In the *Movies* page, you'll update the `WebGrid` helper so that it displays a **Delete** link next to each movie to accompany the **Edit** link you added earlier.

As with editing, when you click the **Delete** link, it takes you to a different page, where the movie information is already in a form:

You can then click the button to delete the record permanently.

Adding a Delete Link to the Movie Listing

You'll start by adding a **Delete** link to the `WebGrid` helper. This link is similar to the **Edit** link you added in a previous tutorial.

Open the *Movies.cshtml* file.

Change the `WebGrid` markup in the body of the page by adding a column. Here's the modified markup:

```
@grid.GetHtml(
    tableStyle: "grid",
    headerStyle: "head",
    alternatingRowStyle: "alt",
    columns: grid.Columns(
grid.Column(format: @<a href="~/EditMovie?id=@item.ID">Edit</a>),
grid.Column("Title"),
grid.Column("Genre"),
grid.Column("Year"),
grid.Column(format: @<a href="~/DeleteMovie?id=@item.ID">Delete</a>)
    )
)
```

The new column is this one:

```
grid.Column(format: @<a href="~/DeleteMovie?id=@item.ID">Delete</a>)
```

The way the grid is configured, the **Edit** column is leftmost in the grid and the **Delete** column is rightmost. (There's a comma after the `Year` column now, in case you didn't notice that.) There's nothing special about where these link columns go, and you could as easily put them next to each other. In this case, they're separate to make them harder to get mixed up.

The new column shows a link (`<a>` element) whose text says "Delete". The target of the link (its `href` attribute) is code that ultimately resolves to something like this URL, with the `id` value different for each movie:

```
http://localhost:43097/DeleteMovie?id=7
```

This link will invoke a page named *DeleteMovie* and pass it the ID of the movie you've selected.

This tutorial won't go into detail about how this link is constructed, because it's almost identical to the **Edit** link from the previous tutorial (Updating Database Data in ASP.NET Web Pages).

Creating the Delete Page

Now you can create the page that will be the target for the **Delete** link in the grid.

> **NOTE**
>
> **Important** The technique of first selecting a record to delete and then using a separate page and button to confirm the process is extremely important for security. As you've read in previous tutorials, making *any* sort of change to your website should *always* be done using a form — that is, using an HTTP POST operation. If you made it possible to change the site just by clicking a link (that is, using a GET operation), people could make simple requests to your site and delete your data. Even a search-engine crawler that's indexing your site could inadvertently delete data just by following links.
>
> When your app lets people change a record, you have to present the record to the user for editing anyway. But you might be tempted to skip this step for deleting a record. Don't skip that step, though. (It's also helpful for users to see the record and confirm that they're deleting the record that they intended.)
>
> In a subsequent tutorial set, you'll see how to add login functionality so a user would have to log in before deleting a record.

Create a page named *DeleteMovie.cshtml* and replace what's in the file with the following markup:

```
<html>
<head>
  <title>Delete a Movie</title>
</head>
<body>
      <h1>Delete a Movie</h1>
        @Html.ValidationSummary()
      <p><a href="~/Movies">Return to movie listing</a></p>

      <form method="post">
        <fieldset>
        <legend>Movie Information</legend>

        <p><span>Title:</span>
         <span>@title</span></p>

        <p><span>Genre:</span>
         <span>@genre</span></p>

        <p><span>Year:</span>
          <span>@year</span></p>

        <input type="hidden" name="movieid" value="@movieId" />
        <p><input type="submit" name="buttonDelete" value="Delete Movie" /></p>
        </fieldset>
      </form>
    </body>
</html>
```

This markup is like the *EditMovie* pages, except that instead of using text boxes (`<input type="text">`), the markup includes `<span>` elements. There's nothing here to edit. All you have to do is display the movie details so that users can make sure that they're deleting the right movie.

The markup already contains a link that lets the user return to the movie listing page.

As in the *EditMovie* page, the ID of the selected movie is stored in a hidden field. (It's passed into the page in the

first place as a query string value.) There's an `Html.ValidationSummary` call that will display validation errors. In this case, the error might be that no movie ID was passed to the page or that the movie ID is invalid. This situation could occur if someone ran this page without first selecting a movie in the *Movies* page.

The button caption is **Delete Movie**, and its name attribute is set to `buttonDelete`. The `name` attribute will be used in the code to identify the button that submitted the form.

You'll have to write code to 1) read the movie details when the page is first displayed and 2) actually delete the movie when the user clicks the button.

Adding Code to Read a Single Movie

At the top of the *DeleteMovie.cshtml* page, add the following code block:

```
@{
    var title = "";
    var genre = "";
    var year = "";
    var movieId = "";

    if(!IsPost){
        if(!Request.QueryString["ID"].IsEmpty() && Request.QueryString["ID"].IsInt()){
            movieId = Request.QueryString["ID"];
            var db = Database.Open("WebPagesMovies");
            var dbCommand = "SELECT * FROM Movies WHERE ID = @0";
            var row = db.QuerySingle(dbCommand, movieId);
            if(row != null) {
                title = row.Title;
                genre = row.Genre;
                year = row.Year;
            }
            else{
                Validation.AddFormError("No movie was found for that ID.");
            }
        }
        else{
            Validation.AddFormError("No movie was found for that ID.");
        }
    }
}
```

This markup is the same as the corresponding code in the *EditMovie* page. It gets the movie ID out of the query string and uses the ID to read a record from the database. The code includes the validation test (`IsInt()` and `row != null`) to make sure that the movie ID being passed to the page is valid.

Remember that this code should only run the first time the page runs. You don't want to re-read the movie record from the database when the user clicks the **Delete Movie** button. Therefore, code to read the movie is inside a test that says `if(!IsPost)` — that is, *if the request is not a post operation (form submission)*.

Adding Code to Delete the Selected Movie

To delete the movie when the user clicks the button, add the following code just inside the closing brace of the `@` block:

```
if(IsPost && !Request["buttonDelete"].IsEmpty()){
    movieId = Request.Form["movieId"];
    var db = Database.Open("WebPagesMovies");
    var deleteCommand = "DELETE FROM Movies WHERE ID = @0";
    db.Execute(deleteCommand, movieId);
    Response.Redirect("~/Movies");
}
```

This code is similar to the code for updating an existing record, but simpler. The code basically runs a SQL `Delete` statement.

As in the *EditMovie* page, the code is in an `if(IsPost)` block. This time, the `if()` condition is a little more complicated:

```
if(IsPost && !Request["buttonDelete"].IsEmpty())
```

There are two conditions here. The first is that the page is being submitted, as you've seen before — `if(IsPost)`.

The second condition is `!Request["buttonDelete"].IsEmpty()`, meaning that the request has an object named `buttonDelete`. Admittedly, it's an indirect way of testing which button submitted the form. If a form contains multiple submit buttons, only the name of the button that was clicked appears in the request. Therefore, logically, if the name of a particular button appears in the request — or as stated in the code, if that button isn't empty — that's the button that submitted the form.

The `&&` operator means "and" (logical AND). Therefore the entire `if` condition is ...

This request is a post (not a first-time request)

AND

The `buttonDelete` *button was the button that submitted the form.*

This form (in fact, this page) contains only one button, so the additional test for `buttonDelete` is technically not required. Still, you're about to perform an operation that will permanently remove data. So you want to be as sure as possible that you're performing the operation only when the user has explicitly requested it. For example, suppose that you expanded this page later and added other buttons to it. Even then, the code that deletes the movie will run only if the `buttonDelete` button was clicked.

As in the *EditMovie* page, you get the ID from the hidden field and then run the SQL command. The syntax for the `Delete` statement is:

`DELETE FROM table WHERE ID = value`

It's vital to include the `WHERE` clause and the ID. If you leave out the WHERE clause, *all the records in the table will be deleted*. As you have seen, you pass the ID value to the SQL command by using a placeholder.

Testing the Movie Delete Process

Now you can test. Run the *Movies* page, and click **Delete** next to a movie. When the *DeleteMovie* page appears, click **Delete Movie**.

When you click the button, the code deletes the movies and returns to the movie listing. There you can search for the deleted movie and confirm that it's been deleted.

Coming Up Next

The next tutorial shows you how to give all the pages on your site a common look and layout.

Complete Listing for Movie Page (Updated with Delete Links)

```
@{
    var db = Database.Open("WebPagesMovies") ;
    var selectCommand = "SELECT * FROM Movies";
    var searchTerm = "";

    if(!Request.QueryString["searchGenre"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Genre = @0";
        searchTerm = Request.QueryString["searchGenre"];
    }

    if(!Request.QueryString["searchTitle"].IsEmpty() ) {
      selectCommand = "SELECT * FROM Movies WHERE Title LIKE @0";
      searchTerm = "%" + Request.QueryString["searchTitle"] + "%";
    }

    var selectedData = db.Query(selectCommand, searchTerm);
    var grid = new WebGrid(source: selectedData, defaultSort: "Genre", rowsPerPage:3);
}
<!DOCTYPE html>

Introducing ASP.NET Web Pages - Creating a Consistent Layout

2/20/2020 • 16 minutes to read • Edit Online

by Tom FitzMacken

This tutorial shows you how to use *layouts* to create a consistent look for the pages on a site that uses ASP.NET Web Pages. It assumes you have completed the series through Deleting Database Data in ASP.NET Web Pages.

What you'll learn:

- What a layout page is.
- How to combine layout pages with dynamic content.
- How to pass values to a layout page.

About Layouts

The pages you've created so far have all been complete, standalone pages. They all belong to the same site, but they don't have any common elements or a standard look.

Most sites do have a consistent look and layout. For example, if you go to the Microsoft.com/web site and look around, you see that the pages all adhere to an overall layout and to a visual theme:

An *inefficient* way to create this layout would be to define a header, navigation bar, and footer separately on each of your pages. You'd be duplicating the same markup each time. If you wanted to change something (for example, update the footer), you'd have to change each page separately.

That's where *layout pages* come in. In ASP.NET Web Pages, you can define a layout page that provides an overall container for pages on your site. For example, the layout page can contain the header, navigation area, and footer. The layout page includes a placeholder where the main content goes.

You can then define individual content pages that contain the markup and the code for only that page. Content pages don't have to be complete HTML pages; they don't even have to have a `<body>` element. They also have a line of code that tells ASP.NET what layout page you want to display the content in. Here's a picture that shows roughly how this relationship works:

This interaction is easy to understand when you see it in action. In this tutorial, you'll change your movies pages to use a layout.

Adding a Layout Page

You'll start by creating a layout page that defines a typical page layout with a header, footer, and an area for the main content. In the WebPagesMovies site, add a CSHTML page named *_Layout.cshtml*.

The leading underscore (`_`) character is significant. If a page's name starts with an underscore, ASP.NET won't directly send that page to the browser. This convention lets you define pages that are required for your site but that users shouldn't be able to request directly.

Replace the content in the page with the following:

```
<!DOCTYPE html>
<html>
  <head>
    <title>My Movie Site</title>
    <link href="~/Styles/Movies.css" rel="stylesheet" type="text/css" />
  </head>
  <body>
    <div id="container">
        <div id="header">
          <h1>My Movie Site</h1>
        </div>
        <div id="main">
          @RenderBody()
        </div>
        <div id="footer">
          &copy; @DateTime.Now.Year My Movie Site
        </div>
    </div>
  </body>
</html>
```

As you can see, this markup is just HTML that uses `<div>` elements to define three sections in the page plus one more `<div>` element to hold the three sections. The footer contains a bit of Razor code: `@DateTime.Now.Year`, which will render the current year at that location in the page.

Notice that there's a link to a style sheet named *Movies.css*. The style sheet is where the details of the physical layout of the elements will be defined. You'll create that in a moment.

The only unusual feature in this *_Layout.cshtml* page is the `@Render.Body()` line. That's the placeholder where the content will go when this layout is merged with another page.

Adding a .css File

The preferred way to define the actual arrangement (that is, appearance) of elements on the page is to use cascading style sheet (CSS) rules. So you'll create a *.css* file that has the rules for your new layout.

In WebMatrix, select the root of your site. Then in the **Files** tab of the ribbon, click the arrow under the **New** button and then click **New Folder**.

Name the new folder *Styles*.

Inside the new *Styles* folder, create a file named *Movies.css*.

Replace the contents of the new *.css* file with the following:

```
html{ height:100%; margin:0; padding:0; }

body {
  height:60%;
  font-family:'Trebuchet MS',  'Arial', 'Helvetica', 'sans-serif';
  font-size:10pt;
  background-color: LightGray;
  line-height:1.6em;
}

h1{ font-size:1.6em; }
h2{ font-size:1.4em; }

#container{
   min-height:100%;
   position:relative;
   left:10%;
}

#header{
  padding:8px;
  width:80%;
  background-color:#4b6c9e;
  color:White;
}

#main{
  width:80%;
  padding: 8px;
  padding-bottom:4em;
  background-color:White;
}

#footer{
  width:80%;
  height:2em;
  padding:8px;
  margin-top:-2em;
  background-color:LightGray;
}

.head { background-color: #E8E8E8; font-weight: bold; color: #FFF; }
.grid th, .grid td { border: 1px solid #C0C0C0; padding: 5px; }
.alt { background-color: #E8E8E8; color: #000; }
.selected {background-color:Yellow;}
span.caption {width:100px;}
span.dataDisplay {font-weight:bold;}
```

We won't say much about these CSS rules, except to note two things. One is that in addition to setting fonts and sizes, the rules use absolute positioning to establish the location of the header, footer, and main content area. If you're new to positioning in CSS, you can read the CSS Positioning tutorial at the W3Schools site.

The other thing to note is that at the bottom, we've copied the style rules that were originally defined individually in the *Movies.cshtml* file. These rules were used in the Introduction to Displaying Data by Using ASP.NET Web Pages tutorial to make the `WebGrid` helper render markup that added stripes to the table. (If you're going to use a *.css* file for style definitions, you might as well put the style rules for the whole site in it.)

Updating the Movies File to Use the Layout

Now you can update the existing files in your site to use the new layout. Open the *Movies.cshtml* file. At the top, as the first line of code, add the following:

```
Layout = "~/_Layout.cshtml";
```

The page now starts out this way:

```
@{
    Layout = "~/_Layout.cshtml";

    var db = Database.Open("WebPagesMovies") ;
    var selectCommand = "SELECT * FROM Movies";
    var searchTerm = "";

    // Etc.
```

This one line of code tells ASP.NET that when the *Movies* page runs, it should be merged with the *_Layout.cshtml* file.

Since the *Movies.cshtml* file now uses a layout page, you can remove the markup from the *Movies.cshtml* page that's taken care of by the *_Layout.cshtml* file. Take out the `<!DOCTYPE>`, `<html>`, and `<body>` opening and closing tags. Take out the entire `<head>` element and its contents, which includes the style rules for the grid, since you've now got those rules in a *.css* file. While you're at it, change the existing `<h1>` element to an `<h2>` element; you have an `<h1>` element in the layout page already. Change the `<h2>` text to "List Movies".

Normally you wouldn't have to make these sorts of changes in a content page. When you start your site out with a layout page, you create content pages without all these elements to begin with. In this case, though, you're converting a standalone page to one that uses a layout, so there's a bit of cleanup.

When you're finished, the *Movies.cshtml* page will look like the following:

```
@{
    Layout = "~/_Layout.cshtml";

    var db = Database.Open("WebPagesMovies") ;
    var selectCommand = "SELECT * FROM Movies";
    var searchTerm = "";

    if(!Request.QueryString["searchGenre"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Genre = @0";
        searchTerm = Request.QueryString["searchGenre"];
    }

    if(!Request.QueryString["searchTitle"].IsEmpty() ) {
      selectCommand = "SELECT * FROM Movies WHERE Title LIKE @0";
      searchTerm = "%" + Request.QueryString["searchTitle"] + "%";
    }

    var selectedData = db.Query(selectCommand, searchTerm);
    var grid = new WebGrid(source: selectedData, defaultSort: "Genre", rowsPerPage:3);
}
  <h2>List Movies</h2>
  <form method="get">
    <div>
      <label for="searchGenre">Genre to look for:</label>
      <input type="text" name="searchGenre"
         value="@Request.QueryString["searchGenre"]" />
      <input type="Submit" value="Search Genre" /><br/>
      (Leave blank to list all movies.)<br/>
    </div>
    <div>
       <label for="SearchTitle">Movie title contains the following:</label>
       <input type="text" name="searchTitle" value="@Request.QueryString["searchTitle"]" />
       <input type="Submit" value="Search Title" /><br/>
    </div>
  </form>
  <div>
    @grid.GetHtml(
        tableStyle: "grid",
        headerStyle: "head",
        alternatingRowStyle: "alt",
        columns: grid.Columns(
            grid.Column(format: @<a href="~/EditMovie?id=@item.ID">Edit</a>),
            grid.Column("Title"),
            grid.Column("Genre"),
            grid.Column("Year"),
            grid.Column(format: @<a href="~/DeleteMovie?id=@item.ID">Delete</a>)
       )
    )
  </div>
  <p><a href="~/AddMovie">Add a movie</a></p>
```

Testing the Layout

Now you can see what the layout looks like. In WebMatrix, right-click the *Movies.cshtml* page and select **Launch in browser**. When the browser displays the page, it looks like this page:

ASP.NET has merged the content of the Movies.cshtml page into the *_Layout.cshtml* page right where the `RenderBody` method is. And of course the *_Layout.cshtml* page references a *.css* file that defines the look of the page.

Updating the AddMovie Page to Use the Layout

The real benefit of layouts is that you can use them for all the pages in your site. Open the *AddMovie.cshtml* page.

You might remember that the *AddMovie.cshtml* page originally had some CSS rules in it to define the look of validation error messages. Since you have a *.css* file for your site now, you can move those rules to the *.css* file. Remove them from the *AddMovie.cshtml* file and add them to the bottom of the *Movies.css* file. You are moving the following rules:

```
.field-validation-error {
  font-weight:bold;
  color:red;
  background-color:yellow;
 }
.validation-summary-errors{
  border:2px dashed red;
  color:red;
  background-color:yellow;
  font-weight:bold;
  margin:12px;
}
```

Now make the same sorts of changes in *AddMovie.cshtml* that you did for *Movies.cshtml* — add `Layout="~/_Layout.cshtml;` and remove the HTML markup that's now extraneous. Change the `<h1>` element to `<h2>`. When you're done, the page will look like this example:

```
@{
    Layout = "~/_Layout.cshtml";
    Validation.RequireField("title", "You must enter a title");
    Validation.RequireField("genre", "Genre is required");
    Validation.RequireField("year", "You haven't entered a year");

    var title = "";
    var genre = "";
    var year = "";

    if(IsPost){
        if(Validation.IsValid()){
            title = Request.Form["title"];
            genre = Request.Form["genre"];
            year = Request.Form["year"];

            var db = Database.Open("WebPagesMovies");
            var insertCommand =
                "INSERT INTO Movies (Title, Genre, Year) Values(@0, @1, @2)";
            db.Execute(insertCommand, title, genre, year);
            Response.Redirect("~/Movies");
        }
    }
}
  <h2>Add a Movie</h2>
    @Html.ValidationSummary()
 <form method="post">
  <fieldset>
    <legend>Movie Information</legend>
    <p><label for="title">Title:</label>
      <input type="text" name="title" value="@Request.Form["title"]" />
      @Html.ValidationMessage("title")
    </p>

    <p><label for="genre">Genre:</label>
      <input type="text" name="genre" value="@Request.Form["genre"]" />
      @Html.ValidationMessage("genre")
    </p>

    <p><label for="year">Year:</label>
      <input type="text" name="year" value="@Request.Form["year"]" />
      @Html.ValidationMessage("year")
    </p>

    <p><input type="submit" name="buttonSubmit" value="Add Movie" /></p>
  </fieldset>
  </form>
```

Run the page. Now it looks like this illustration:

You want to make similar changes to the pages in the site — *EditMovie.cshtml* and *DeleteMovie.cshtml*. However, before you do, you can make another change to the layout that makes it a little more flexible.

Passing Title Information to the Layout Page

The *_Layout.cshtml* page that you created has a `<title>` element that's set to "My Movie Site". Most browsers display the content of this element as the text on a tab:

This title information is generic. Suppose that you want the title text to be more specific to the current page. (The title text is also used by search engines to determine what your page is about.) You can pass information from a content page like *Movies.cshtml* or *AddMovie.cshtml* to the layout page, and then use that information to customize what the layout page renders.

Open the *Movies.cshtml* page again. In the code at the top, add the following line:

```
Page.Title = "List Movies";
```

The `Page` object is available on all *.cshtml* pages and is for this purpose, namely to share information between a page and its layout.

Open the *_Layout.cshtml* page. Change the `<title>` element so that it looks like this markup:

```
<title>@Page.Title</title>
```

This code renders whatever is in the `Page.Title` property right at that location in the page.

Run the *Movies.cshtml* page. This time the browser tab shows what you passed as the value of `Page.Title`:

If you want, view the page source in the browser. You can see that the `<title>` element is rendered as `<title>List Movies</title>`.

TIP

The Page Object

A useful feature of `Page` is that it's a dynamic object — the `Title` property is not a fixed or reserved name. You can use *any* name for a value of the `Page` object. For example, you could as easily have passed the title by using a property named `Page.CurrentName` or `Page.MyPage`. The only restriction is that the name has to follow the normal rules for what properties can be named. (For example, the name can't contain a space.)

You can pass any number of values by using the `Page` object. If you wanted to pass movie information to the layout page, you could pass values by using something like `Page.MovieTitle` and `Page.Genre` and `Page.MovieYear`. (Or any other names that you invented to store the information.) The only requirement — which is probably obvious — is that you have to use the same names in the content page and the layout page.

The information you pass by using the `Page` object isn't limited to just text to display on the layout page. You can pass a value to the layout page, and then code in the layout page can use the value to decide whether to display a section of the page, what *.css* file to use, and so on. The values you pass in the `Page` object are like any other values that you use in code. It's just that the values originate in the content page and are passed to the layout page.

Open the *AddMovie.cshtml* page and add a line to the top of the code that provides a title for the *AddMovie.cshtml* page:

```
Page.Title = "Add a Movie";
```

Run the *AddMovie.cshtml* page. You see the new title there:

Updating the Remaining Pages to Use the Layout

Now you can finish the remaining pages in your site so that they use the new layout. Open *EditMovie.cshtml* and *DeleteMovie.cshtml* in turn and make the same changes in each.

Add the line of code that links to the layout page:

```
Layout = "~/_Layout.cshtml";
```

Add a line to set the title of the page:

```
Page.Title = "Edit a Movie";
```

or:

```
Page.Title = "Delete a Movie";
```

Remove all the extraneous HTML markup — basically, leave only the bits that are inside the `<body>` element (plus the code block at the top).

Change the `<h1>` element to be an `<h2>` element.

When you've made these changes, test each and make sure that it's displaying properly and that the title is correct.

Parting Thoughts About Layout Pages

In this tutorial you created a *_Layout.cshtml* page and used the `RenderBody` method to merge content from another page. That's the basic pattern for using layouts in Web Pages.

Layout pages have additional features that we didn't cover here. For example, you can nest layout pages — one layout page can in turn reference another. Nested layouts can be useful if you're working with subsections of a site that require different layouts. You can also use additional methods (for example, `RenderSection`) to set up named sections in the layout page.

The combination of layout pages and *.css* files is powerful. As you'll see in the next tutorial series, in WebMatrix you can create a site based on a *template*, which gives you a site that has prebuilt functionality in it. The templates make good use of layout pages and CSS to create sites that look great and that have features like menus. Here's a screenshot of the home page from a site based on a template, showing features that use layout pages and CSS:

Complete Listing for Movie Page (Updated to Use a Layout Page)

```
@{
    Layout = "~/_Layout.cshtml";
    Page.Title = "List Movies";

    var db = Database.Open("WebPagesMovies") ;
    var selectCommand = "SELECT * FROM Movies";
    var searchTerm = "";

    if(!Request.QueryString["searchGenre"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Genre = @0";
        searchTerm = Request.QueryString["searchGenre"];
    }

    if(!Request.QueryString["searchTitle"].IsEmpty() ) {
        selectCommand = "SELECT * FROM Movies WHERE Title LIKE @0";
        searchTerm = "%" + Request.QueryString["searchTitle"] + "%";
    }

    var selectedData = db.Query(selectCommand, searchTerm);
    var grid = new WebGrid(source: selectedData, defaultSort: "Genre", rowsPerPage:3);
}

<h2>List Movies</h2>

            var db = Database.Open("WebPagesMovies");
            var updateCommand = "UPDATE Movies SET Title=@0, Genre=@1, Year=@2 WHERE Id=@3";
            db.Execute(updateCommand, title, genre, year, movieId);
            Response.Redirect("~/Movies");
        }
    }
}

<h2>Edit a Movie</h2>
@Html.ValidationSummary()
<form method="post">
<fieldset>
    <legend>Movie Information</legend>

    <p><label for="title">Title:</label>
        <input type="text" name="title" value="@title" /></p>

    <p><label for="genre">Genre:</label>
        <input type="text" name="genre" value="@genre" /></p>

    <p><label for="year">Year:</label>
        <input type="text" name="year" value="@year" /></p>

    <input type="hidden" name="movieid" value="@movieId" />

    <p><input type="submit" name="buttonSubmit" value="Submit Changes" /></p>
</fieldset>
</form>
<p><a href="~/Movies">Return to movie listing</a></p>
```

Coming Up Next

In the next tutorial, you'll learn how to publish your site to the Internet so everyone can see it.

Introducing ASP.NET Web Pages - Publishing a Site by Using WebMatrix

9/16/2020 • 10 minutes to read • Edit Online

by Tom FitzMacken

This tutorial is the final installment in the tutorial set that introduces ASP.NET Web Pages and Microsoft WebMatrix. It discusses how to publish your site to the Internet so that others can work with it. It assumes you have completed the series through Creating a Consistent Look for ASP.NET Web Pages Sites.

You'll learn how to publish your site using:

- Microsoft Azure
- Web Hosting Company

About Publishing Your Site

Up to now, you've done all your work on a local computer, including testing your pages. To run your *.cshtml* pages, you've used the web server that's built into WebMatrix, namely IIS Express. But of course no one can see the site you've created except you. To let others work with your site, you have to publish it to the Internet.

Unless you have access to a public web server already, publishing means that you have to have an account with a *cloud platform* or a *hosting provider*. A cloud platform, such as Microsoft Azure, provides on-demand infrastructure for your applications. A hosting provider is a company that owns publicly accessible web servers and that will rent you space for your site. Hosting plans run from a few dollars a month (or even free) for small sites to many hundreds of dollars a month for high-volume commercial websites.

> **NOTE**
>
> You might have access to a public web server via the internet service provider (ISP) that you use to get internet service at home. However, your hosting provider must support ASP.NET Web Pages. Many ISPs don't, but it's always worth checking.

In this tutorial, we'll give you an overview of how to publish. It's not practical to provide exact details for everything, because the process differs a bit for every hosting provider. But you'll get a good idea of how the process works.

This tutorial contains four sections:

1. Setting up the default page
2. Publishing (choose one of the following)
   a. Publishing Your Site to Microsoft Azure
   b. Publishing Your Site to a Web Hosting Company
3. Updating the Live Site: Republishing

Setting up the default page

When a user navigates to the base address for your web site, the default page for your site is displayed to the user. For example, when *Default.htm* is set as the default page for the site at `www.contoso.com`, then navigating to `www.contoso.com` is the same as navigating to `www.contoso.com/Default.htm`.

Currently, your site uses **Default.cshtml** as the default page. This page is fine for your default page, but in this tutorial you have not added any content to that page so it would display a blank page. Open Default.cshtml and replace the content with the following code.

```
@{
    Layout = "~/_Layout.cshtml";
    Page.Title = "Welcome to Movie site";
}

<p><a href="~/Movies">Go to movie listing</a></p>
```

Now your site is ready for publication. First, you will see how to deploy the site to Azure, and then how to deploy it to a web hosting company. Either option works for your web site, and you only need to follow one of the deployment options.

Publishing Your Site to Microsoft Azure

This tutorial will first show you how to deploy your site to Microsoft Azure. By signing in with a Microsoft account, you can create up to 10 free sites on Azure. These free sites provide a convenient way to test your sites. You can always delete this example site later to avoid using all of your free sites. You can create a free trial account in just a couple of minutes. For details, see Azure Free Trial.

In the WebMatrix ribbon, click the **Publish** button.

The **Publish Your Site** dialog box is displayed. If you have not signed in to your Microsoft account, the dialog box will contain a **Get started with Azure** link. Click this link.

If you have not signed in to a Microsoft account, you are again given the opportunity to sign in. You must sign in to a Microsoft account to publish your site on Azure.

After signing in to your Microsoft account, the dialog box contains links to create a new site on Azure or connect to one of your existing sites on Azure.

Select **Create a new site**.

If you named your project **WebPagesMovies**, the default name for your site will be **webpagesmovies.azurewebsites.net**. This default name is most likely not available, as indicated by the red exclamation mark.

Change the site name to something that is available, and select a location that is close to your location.

Click **OK**.

WebMatrix performss a test to determine if the server is compatible with your site.

Select **Continue**.

The results of the compatibility test are displayed.

Select **Continue**.

WebMatrix displays the files and databases that will be published to the site. Since this is the first time you are publishing the site, all of the files are listed. You can uncheck a file that is not ready to be published. In the subsequent publications, only the files that have changed will be displayed. See Updating the Live Site: Republishing.

Select **Continue**.

After the site has been deployed to Azure, a message is displayed that indicates the deployment has completed.

Your site and database have been published to Azure, and are now available to the public. Click the link in the message indicating publishing has completed, and you will now see your deployed site. You or anyone with Internet access can add or modify records in the database.

Publishing Your Site to a Web Hosting Company

If you decide to not publish to Azure, you can instead publish your site to a web hosting company.

Click the **Find web hosting** link.

You go to a page on the Microsoft site that lists hosting providers that support ASP.NET.

Obviously, it can be difficult to know now exactly what hosting features you might require over the long term. Here are a couple of things to consider:

- For purposes of the WebPagesMovies site, you don't have to have a separate add-on for SQL Server, which often costs extra. In your site, you're using SQL Server Compact Edition, which is self-contained. However, you might need SQL Server access for some future website work you do. If you think you might, make sure that you can add SQL Server capability later.
- Check whether the hosting provider supports the Web Deploy publishing protocol. You can publish by using FTP protocol, but it's more convenient to use Web Deploy.

Some sites offer a free trial period. A free trial is a good way to try publishing and hosting while you're still experimenting with WebMatrix and ASP.NET Web Pages.

Pick one that you like. For this tutorial, we selected DiscountASP.NET, because while we were creating the tutorial, that company had a promotion that let people host a site free for a few months.

> **NOTE**
> Our choice of a hosting provider for this tutorial shouldn't be interpreted as an endorsement of that company over any other. But we had to pick one for illustration, and DiscountASP.NET is one of the many companies that supports ASP.NET Web Pages and the Web Deploy protocol for publishing.

Typically, after you've signed up with the hosting provider, the company sends you an email that contains a user name and password, the URL of the web server, and so on. If the hosting company supports Web Deploy protocol, they might send you a file that contains publish settings, or let you download one. A publish settings file simplifies the process for you.

When you've signed up and are ready to publish, click the **Publish** button in the WebMatrix ribbon. The **Publish Settings** dialog box is displayed.

If the hosting provider sent you a publish settings file, click the **Import publish settings** link and import the file. If you don't have a publish settings file, fill in the fields by using the values that the hosting company sent you in email. Here's what the **Publish Settings** dialog box might look like when you're done:

Click **Validate Connection**. If everything is ok, the dialog box reports **Connected successfully**, which means it can communicate with the hosting provider's server.

If there's a problem, WebMatrix does its best to tell you what the problem is:

Click **Save** to save your settings. WebMatrix offers to perform a test to make sure that it can communicate correctly with the hosting site:

Click **Yes**. WebMatrix uploads some sample files to the hosting provider. When the compatibility test is done, WebMatrix reports the results:

If you're ready to go, go ahead and click **Continue** to start the publish process for real. WebMatrix figures out what files are in your site and are already on the host server (right now, none) and gives you a preview of the publish process:

The list of files to publish includes the web pages that you've created like *Movies.cshtml*. The list also includes files for helpers that you've installed, the files to run SQL Server Compact Edition for your database, and so on. As a result, the initial publish process can be substantial.

Click **Continue**. WebMatrix copies your files to the hosting provider's server. When it's done, the results are reported in the status bar:

To see your live site, click the link in the status bar. Add *Movies* to the URL, and you'll see the *Movies.cshtml* file that you created:

Updating the Live Site: Republishing

Once you've published your site (to either Azure or a web hosting company), there are two copies of it — the version on your computer and the version on the service provider. You'll probably want to continue developing the site (if nothing else, as part of the next tutorial set). When you do, you have to republish your site in order to copy changes from your computer to the service provider. The publish process in WebMatrix can determine what files have changed on your site and publish just those files.

To see how republishing works, open the *Movies.cshtml* site, make some small change, and then save the file. For example, change the title to `Movies - Updated`.

Click the **Publish** button in the ribbon. WebMatrix determines what's changed and shows you a preview of the files it will publish.

IMPORTANT

By default, WebMatrix publishes your database (*.sdf* file) only the first time you publish the site. Once your site is published and people are interacting with the website, the database on the live site typically has the site's real data. You have to be very careful not to overwrite the live database with the *.sdf* file that's on your computer, which usually contains only test data. That's why you see the warning **Publishing will overwrite any remote databases**, and why the check box for *WebPagesMovies.sdf* is cleared by default.

Click **Continue**. WebMatrix publishes the changed files and shows you a success message, like it did the first time you published.

Go to the live site (you can click the link in the success message if it's still showing) and verify that your change has been published.

> **TIP**
>
> **Editing Files Remotely**
>
> As an alternative to changing your site and then republishing, you can edit remote files directly in WebMatrix. In this scenario, you open a file that's on the service provider, and WebMatrix downloads a copy of it for you to edit. Every time you save the file, WebMatrix sends the changes to the site.
>
> Remote editing is an easy way to make changes to your live site. However, the changes you make this way aren't synchronized with the files in your local site. To synchronize the local files with the remote site, you can download the remote files. This process works much like publishing, except in reverse.
>
> We won't describe more about the remote-editing and remote-download facilities of WebMatrix here. They're quite useful if multiple people have to work on the same site on different computers. For more information, see Publish and Edit a Remote Site with WebMatrix 2 Beta.

Routing

2/20/2020 • 2 minutes to read • Edit Online

How to customize the URLs used by a Web Pages application.

- Creating Readable URLs in ASP.NET Web Pages Sites

Creating Readable URLs in ASP.NET Web Pages (Razor) Sites

2/20/2020 • 3 minutes to read • Edit Online

by Tom FitzMacken

This article describes routing in an ASP.NET Web Pages (Razor) website, and how this lets you use URLs that are more readable and better for SEO.

What you'll learn:

- How ASP.NET uses routing to let you use more readable and searchable URLs.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

About Routing

The URLs for the pages in your site can have an impact on how well the site works. A URL that's "friendly" can make it easier for people to use the site. It can also help with search-engine optimization (SEO) for the site. ASP.NET websites include the ability to use friendly URLs automatically.

ASP.NET lets you create meaningful URLs that describe user actions instead of just pointing to a file on the server. Consider these URLs for a fictional blog:

- `http://www.contoso.com/Blog/blog.cshtml?categories=hardware`
- `http://www.contoso.com//Blog/blog.cshtml?startdate=2009-11-01&enddate=2009-11-30`

Compare those URLs to the following ones:

- `http://www.contoso.com/Blog/categories/hardware/`
- `http://www.contoso.com/Blog/2009/November`

In the first pair, a user would have to know that the blog is displayed using the *blog.cshtml* page, and would then have to construct a query string that gets the right category or date range. The second set of examples is much easier to comprehend and create.

The URLs for the first example also point directly to a specific file (*blog.cshtml*). If for some reason the blog were moved to another folder on the server, or if the blog were rewritten to use a different page, the links would be wrong. The second set of URLs doesn't point to a specific page, so even if the blog implementation or location changes, the URLs would still be valid.

In ASP.NET Web Pages, you can create friendlier URLs like those in the above examples because ASP.NET uses *routing*. Routing creates logical mapping from a URL to a page (or pages) that can fulfill the request. Because the mapping is logical (not physical, to a specific file), routing provides great flexibility in how you define the URLs for your site.

How Routing Works

When ASP.NET processes a request, it reads the URL to determine how to route it. ASP.NET tries to match individual segments of the URL to files on disk, going from left to right. If there's a match, anything remaining in the URL is passed to the page as *path information*.

Imagine that someone makes a request using this URL:

`http://www.contoso.com/a/b/c`

The search goes like this:

1. Is there a file with the path and name of */a/b/c.cshtml*? If so, run that page and pass no information to it. Otherwise ...
2. Is there a file with the path and name of */a/b.cshtml*? If so, run that page and pass the value `c` to it. Otherwise ...
3. Is there a file with the path and name of */a.cshtml*? If so, run that page and pass the value `b/c` to it.

If the search found no exact matches for *.cshtml* files in their specified folders, ASP.NET continues looking for these files in turn:

1. */a/b/c/default.cshtml* (no path information).
2. */a/b/c/index.cshtml* (no path information).

> **NOTE**
> To be clear, requests for specific pages (that is, requests that include the *.cshtml* filename extension) work just like you'd expect. A request like `http://www.contoso.com/a/b.cshtml` will run the page *b.cshtml* just fine.

Inside a page, you can get the path information via the page's `UrlData` property, which is a dictionary. Imagine that you have a file named *ViewCustomers.cshtml* and your site gets this request:

`http://mysite.com/myWebSite/ViewCustomers/1000`

As described in the rules above, the request will go to your page. Inside the page, you can use code like the following to get and display the path information (in this case, the value "1000"):

```
<!DOCTYPE html>
<html>
    <head>
        <title>URLData</title>
    </head>
    <body>
      Customer ID: @UrlData[0].ToString()
    </body>
</html>
```

> **NOTE**
> Because routing doesn't involve complete file names, there can be ambiguity if you have pages that have the same name but different file-name extensions (for example, *MyPage.cshtml* and *MyPage.html*). In order to avoid problems with routing, it's best to make sure that you don't have pages in your site whose names differ only in their extension.

Working with HTML Forms in ASP.NET Web Pages (Razor) Sites

2/20/2020 • 10 minutes to read • Edit Online

by Tom FitzMacken

This article describes how to process an HTML form (with text boxes and buttons) when you are working in an ASP.NET Web Pages (Razor) website.

What you'll learn:

- How to create an HTML form.
- How to read user input from the form.
- How to validate user input.
- How to restore form values after the page is submitted.

These are the ASP.NET programming concepts introduced in the article:

- The `Request` object.
- Input validation.
- HTML encoding.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

Creating a Simple HTML Form

1. Create a new website.

2. In the root folder, create a web page named *Form.cshtml* and enter the following markup:

```
<!DOCTYPE html>
<html>
    <head>
        <title>Customer Form</title>
    </head>
    <body>
      <form method="post" >
        <fieldset>
          <legend>Add Customer</legend>
          <div>
            <label for="CompanyName">Company Name:</label>
            <input type="text" name="CompanyName" value="" />
          </div>
          <div>
            <label for="ContactName">Contact Name:</label>
            <input type="text" name="ContactName" value="" />
          </div>
          <div>
            <label for="Employees">Employee Count:</label>
            <input type="text" name="Employees" value="" />
          </div>
          <div>
            <label> </label>
            <input type="submit" value="Submit" class="submit" />
          </div>
        </fieldset>
      </form>
    </body>
</html>
```

3. Launch the page in your browser. (In WebMatrix, in the **Files** workspace, right-click the file and then select **Launch in browser**.) A simple form with three input fields and a **Submit** button is displayed.

At this point, if you click the **Submit** button, nothing happens. To make the form useful, you have to add some code that will run on the server.

Reading User Input from the Form

To process the form, you add code that reads the submitted field values and does something with them. This procedure shows you how to read the fields and display the user input on the page. (In a production application, you generally do more interesting things with user input. You'll do that in the article about working with databases.)

1. At the top of the *Form.cshtml* file, enter the following code:

```
@{
    if (IsPost) {
        string companyname = Request.Form["companyname"];
        string contactname = Request.Form["contactname"];
        int employeecount = Request.Form["employees"].AsInt();

        <text>
          You entered: <br />
          Company Name: @companyname <br />
          Contact Name: @contactname <br />
          Employee Count: @employeecount <br />
        </text>
    }
}
```

When the user first requests the page, only the empty form is displayed. The user (which will be you) fills in the form and then clicks **Submit**. This submits (posts) the user input to the server. By default, the request goes to the same page (namely, *Form.cshtml*).

When you submit the page this time, the values you entered are displayed just above the form:

Look at the code for the page. You first use the `IsPost` method to determine whether the page is being posted — that is, whether a user clicked the **Submit** button. If this is a post, `IsPost` returns true. This is the standard way in ASP.NET Web Pages to determine whether you're working with an initial request (a GET request) or a postback (a POST request). (For more information about GET and POST, see the sidebar "HTTP GET and POST and the IsPost Property" in Introduction to ASP.NET Web Pages Programming Using the Razor Syntax.)

Next, you get the values that the user filled in from the `Request.Form` object, and you put them in variables for later. The `Request.Form` object contains all the values that were submitted with the page, each identified by a key. The key is the equivalent to the `name` attribute of the form field that you want to read. For example, to read the `companyname` field (text box), you use `Request.Form["companyname"]`.

Form values are stored in the `Request.Form` object as strings. Therefore, when you have to work with a value as a number or a date or some other type, you have to convert it from a string to that type. In the example, the `AsInt` method of the `Request.Form` is used to convert the value of the employees field (which contains an employee count) to an integer.

2. Launch the page in your browser, fill in the form fields, and click **Submit**. The page displays the values you entered.

TIP

HTML Encoding for Appearance and Security

HTML has special uses for characters like `<`, `>`, and `&`. If these special characters appear where they're not expected, they can ruin the appearance and functionality of your web page. For example, the browser interprets the `<` character (unless it's followed by a space) as the beginning of an HTML element, like `<b>` or `<input ...>`. If the browser doesn't recognize the element, it simply discards the string that begins with `<` until it reaches something that it again recognizes. Obviously, this can result in some weird rendering in the page.

HTML encoding replaces these reserved characters with a code that browsers interpret as the correct symbol. For example, the `<` character is replaced with `<` and the `>` character is replaced with `>`. The browser renders these replacement strings as the characters that you want to see.

It's a good idea to use HTML encoding any time you display strings (input) that you got from a user. If you don't, a user can try to get your web page to run a malicious script or do something else that compromises your site security or that's just not what you intend. (This is particularly important if you take user input, store it someplace, and then display it later — for example, as a blog comment, user review, or something like that.)

To help prevent these problems, ASP.NET Web Pages automatically HTML-encodes any text content that you output from your code. For example, when you display the content of a variable or an expression using code such as `@MyVar`, ASP.NET Web Pages automatically encodes the output.

Validating User Input

Users make mistakes. You ask them to fill in a field, and they forget to, or you ask them to enter the number of employees and they type a name instead. To make sure that a form has been filled in correctly before you process it, you validate the user's input.

This procedure shows how to validate all three form fields to make sure the user didn't leave them blank. You also check that the employee count value is a number. If there are errors, you'll display an error message that tells the user what values didn't pass validation.

1. In the *Form.cshtml* file, replace the first block of code with the following code:

```
@{
    Validation.RequireField("companyname", "Company name is required.");
    Validation.RequireField("contactname", "Contact name is required.");
    Validation.RequireField("employees", "Employee count is required.");
    Validation.Add("employees", Validator.Integer());

    if (IsPost)  {
        var companyname = Request.Form["companyname"];
        var contactname = Request.Form["contactname"];
        var employeecount = Request.Form["employees"];
        if(Validation.IsValid()){
            <text>
              You entered: <br />
              Company Name: @companyname <br />
              Contact Name: @contactname <br />
              Employee Count: @employeecount <br />
            </text>
        }
    }
}
```

   To validate user input, you use the `Validation` helper. You register required fields by calling `Validation.RequireField`. You register other types of validation by calling `Validation.Add` and specifying the field to validate and the type of validation to perform.

When the page runs, ASP.NET does all the validation for you. You can check the results by calling `Validation.IsValid`, which returns true if everything passed and false if any field failed validation. Typically, you call `Validation.IsValid` before you perform any processing on the user input.

2. Update the `<body>` element by adding three calls to the `Html.ValidationMessage` method, like this:

```
<body>
  <form method="post">
    <fieldset>
      <legend>Add Customer</legend>
      <div>
         <label for="CompanyName">Company Name:</label>
         <input type="text" name="CompanyName" value="" />
         @Html.ValidationMessage("companyname")
      </div>
      <div>
         <label for="ContactName">Contact Name:</label>
         <input type="text" name="ContactName" value="" />
         @Html.ValidationMessage("contactname")
      </div>
      <div>
         <label for="Employees">Employee Count:</label>
         <input type="text" name="Employees" value="" />
         @Html.ValidationMessage("employees")
      </div>
      <div>
         <label> </label>
         <input type="submit" value="Submit" class="submit" />
      </div>
    </fieldset>
  </form>
</body>
```

To display validation error messages, you can call Html.`ValidationMessage` and pass it the name of the field that you want the message for.

3. Run the page. Leave the fields blank and click **Submit**. You see error messages.

4. Add a string (for example, "ABC") to the **Employee Count** field and click **Submit** again. This time you see an error that indicates that the string isn't in the right format, namely, an integer.

ASP.NET Web Pages provides more options for validating user input, including the ability to automatically perform validation using client script, so that users get immediate feedback in the browser. See the Additional Resources section later for more information.

Restoring Form Values After Postbacks

When you tested the page in the previous section, you might have noticed that if you had a validation error, everything you entered (not just the invalid data) was gone, and you had to re-enter values for all the fields. This illustrates an important point: when you submit a page, process it, and then render the page again, the page is re-created from scratch. As you saw, this means that any values that were in the page when it was submitted are lost.

You can fix this easily, however. You have access to the values that were submitted (in the `Request.Form` object, so you can fill those values back into the form fields when the page is rendered.

1. In the *Form.cshtml* file, replace the `value` attributes of the `<input>` elements using the `value` attribute.:

```
<!DOCTYPE html>
<html>
  <head>
    <title>Customer Form</title>
  </head>
  <body>
    <form method="post">
      <fieldset>
        <legend>Add Customer</legend>
        <div>
          <label for="CompanyName">Company Name:</label>
          <input type="text" name="CompanyName"
                 value="@Request.Form["companyname"]"  />
          @Html.ValidationMessage("companyname")
        </div>
        <div>
         <label for="ContactName">Contact Name:</label>
         <input type="text" name="ContactName"
                value="@Request.Form["contactname"]" />
         @Html.ValidationMessage("contactname")
        </div>
        <div>
         <label for="Employees">Employee Count:</label>
         <input type="text" name="Employees"
                value="@Request.Form["employees"]" />
         @Html.ValidationMessage("employees")
        </div>
        <div>
          <label> </label>
          <input type="submit" value="Submit" class="submit" />
        </div>
    </fieldset>
  </form>
</body>
```

   The `value` attribute of the `<input>` elements has been set to dynamically read the field value out of the `Request.Form` object. The first time that the page is requested, the values in the `Request.Form` object are all empty. This is fine, because that way the form is blank.

2. Launch the page in your browser, fill in the form fields or leave them blank, and click **Submit**. A page that shows the submitted values is displayed.

Validating User Input in ASP.NET Web Pages (Razor) Sites

2/20/2020 • 10 minutes to read • Edit Online

by Tom FitzMacken

This article discusses how to validate information you get from users — that is, to make sure that users enter valid information in HTML forms in an ASP.NET Web Pages (Razor) site.

What you'll learn:

- How to check that a user's input matches validation criteria that you define.
- How to determine whether all validation tests have passed.
- How to display validation errors (and how to format them).
- How to validate data that doesn't come directly from users.

These are the ASP.NET programming concepts introduced in the article:

- The `Validation` helper.
- The `Html.ValidationSummary` and `Html.ValidationMessage` methods.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

This article contains the following sections:

- Overview of User Input Validation
- Validating User Input
- Adding Client-Side Validation
- Formatting Validation Errors
- Validating Data That Doesn't Come Directly from Users

Overview of User Input Validation

If you ask users to enter information in a page — for example, into a form — it's important to make sure that the values that they enter are valid. For example, you don't want to process a form that's missing critical information.

When users enter values into an HTML form, the values that they enter are strings. In many cases, the values you need are some other data types, like integers or dates. Therefore, you also have to make sure that the values that users enter can be correctly converted to the appropriate data types.

You might also have certain restrictions on the values. Even if users correctly enter an integer, for example, you might need to make sure that the value falls within a certain range.

> **NOTE**
>
> **Important** Validating user input is also important for security. When you restrict the values that users can enter in forms, you reduce the chance that someone can enter a value that can compromise the security of your site.

Validating User Input

In ASP.NET Web Pages 2, you can use the `Validator` helper to test user input. The basic approach is to do the following:

1. Determine which input elements (fields) you want to validate.

   You typically validate values in `<input>` elements in a form. However, it's a good practice to validate all input, even input that comes from a constrained element like a `<select>` list. This helps to make sure that users don't bypass the controls on a page and submit a form.

2. In the page code, add individual validation checks for each input element by using methods of the `Validation` helper.

   To check for required fields, use `Validation.RequireField(field, [error message])` (for an individual field) or `Validation.RequireFields(field1, field2, ...))` (for a list of fields). For other types of validation, use `Validation.Add(field, ValidationType)`. For `ValidationType`, you can use these options:

   `Validator.DateTime ([error message])`
   `Validator.Decimal([error message])`
   `Validator.EqualsTo(otherField [, error message])`
   `Validator.Float([error message])`
   `Validator.Integer([error message])`
   `Validator.Range(min, max [, error message])`
   `Validator.RegEx(pattern [, error message])`
   `Validator.Required([error message])`
   `Validator.StringLength(length)`
   `Validator.Url([error message])`

3. When the page is submitted, check whether validation has passed by checking `Validation.IsValid`:

   ```
   if(IsPost && Validation.IsValid()){
       // Process form submit
   }
   ```

   If there are any validation errors, you skip normal page processing. For example, if the purpose of the page is to update a database, you don't do that until all validation errors have been fixed.

4. If there are validation errors, display error messages in the page's markup by using `Html.ValidationSummary` or `Html.ValidationMessage`, or both.

The following example shows a page that illustrates these steps.

```
@{
    var message="";
    // Specify validation requirements for different fields.
    Validation.RequireField("coursename", "Class name is required");
    Validation.RequireField("credits", "Credits is required");
    Validation.Add("coursename", Validator.StringLength(5));
    Validation.Add("credits", Validator.Integer("Credits must be an integer"));
    Validation.Add("credits", Validator.Range(1, 5, "Credits must be between 1 and 5"));
    Validation.Add("startDate", Validator.DateTime("Start date must be a date"));

    if (IsPost)  {
        // Before processing anything, make sure that all user input is valid.
        if (Validation.IsValid()) {
            var coursename = Request["coursename"];
            var credits = Request["credits"].AsInt();
            var startDate = Request["startDate"].AsDateTime();
            message += @"For Class, you entered " + coursename;
            message += @"<br/>For Credits, you entered " + credits.ToString();
            message += @"<br/>For Start Date, you entered " + startDate.ToString("dd-MMM-yyyy");

            // Further processing here
        }
    }
}
<!DOCTYPE html>
<html lang="en">
<head>
  <title>Validation Example</title>
  <style>
      body {margin: 1in; font-family: 'Segoe UI'; font-size: 11pt; }
   </style>
</head>
<body>
  <h1>Validation Example</h1>
  <p>This example page asks the user to enter information about some classes at school.</p>
  <form method="post">
    @Html.ValidationSummary()
    <div>
      <label for="coursename">Course name: </label>
      <input type="text"
         name="coursename"
         value="@Request["coursename"]"
      />
      @Html.ValidationMessage("coursename")
    </div>

    <div>
      <label for="credits">Credits: </label>
      <input type="text"
         name="credits"
         value="@Request["credits"]"
      />
      @Html.ValidationMessage("credits")
    </div>

    <div>
      <label for="startDate">Start date: </label>
      <input type="text"
         name="startDate"
         value="@Request["startDate"]"
      />
      @Html.ValidationMessage("startDate")
```

```
    </div>

   <div>
      <input type="submit" value="Submit" class="submit" />
    </div>

    <div>
      @if(IsPost){
        <p>@Html.Raw(message)</p>
      }
    </div>
  </form>
</body>
</html>
```

To see how validation works, run this page and deliberately make mistakes. For example, here's what the page looks like if you forget to enter a course name, if you enter an, and if you enter an invalid date:

Adding Client-Side Validation

By default, user input is validated after users submit the page — that is, the validation is performed in server code. A disadvantage of this approach is that users don't know that they've made an error until after they submit the page. If a form is long or complex, reporting errors only after the page is submitted can be inconvenient to the user.

You can add support to perform validation in client script. In that case, the validation is performed as users work in the browser. For example, suppose you specify that a value should be an integer. If a user enters a non-integer value, the error is reported as soon as the user leaves the entry field. Users get immediate feedback, which is convenient for them. Client-based validation can also reduce the number of times that the user has to submit the form to correct multiple errors.

> **NOTE**
> Even if you use client-side validation, validation is always also performed in server code. Performing validation in server code is a security measure, in case users bypass client-based validation.

1. Register the following JavaScript libraries in the page:

```
<script src="https://ajax.aspnetcdn.com/ajax/jQuery/jquery-1.6.2.js">
</script>
<script
src="https://ajax.aspnetcdn.com/ajax/jquery.validate/1.8.1/jquery.validate.js">
</script>
<script src="~/Scripts/jquery.validate.unobtrusive.js">
</script>
```

Two of the libraries are loadable from a content delivery network (CDN), so you don't necessarily have to have them on your computer or server. However, you must have a local copy of *jquery.validate.unobtrusive.js*. If you are not already working with a WebMatrix template (like **Starter Site**) that includes the library, create a Web Pages site that's based on **Starter Site**. Then copy the *.js* file to your current site.

2. In markup, for each element that you're validating, add a call to `Validation.For(field)`. This method emits attributes that are used by client-side validation. (Rather than emitting actual JavaScript code, the method emits attributes like `data-val-...`. These attributes support unobtrusive client validation that uses jQuery to do the work.)

The following page shows how to add client validation features to the example shown earlier.

```
@{
    // Note that client validation as implemented here will work only with
    // ASP.NET Web Pages 2.

    var message="";
    // Specify validation requirements for different fields.
    Validation.RequireField("coursename", "Class name is required");
    Validation.RequireField("credits", "Credits is required");
    Validation.Add("coursename", Validator.StringLength(5));
    Validation.Add("credits", Validator.Integer("Credits must be an integer"));
    Validation.Add("credits", Validator.Range(1, 5, "Credits must be between 1 and 5"));
    Validation.Add("startDate", Validator.DateTime("Start date must be a date"));

    if (IsPost)  {
        // Before processing anything, make sure that all user input is valid.
        if (Validation.IsValid()) {
            var coursename = Request["coursename"];
            var credits = Request["credits"].AsInt();
            var startDate = Request["startDate"].AsDateTime();
            message += @"For Class, you entered " + coursename;
            message += @"<br/>For Credits, you entered " + credits.ToString();
            message += @"<br/>For Start Date, you entered " + startDate.ToString("dd-MMM-yyyy");

            // Further processing here
        }
    }
}
<!DOCTYPE html>
<html lang="en">
<head>
  <title>Validation Example with Client Validation</title>

      body {margin: 1in; font-family: 'Segoe UI'; font-size: 11pt; }
   </style>
    <script src="https://ajax.aspnetcdn.com/ajax/jQuery/jquery-1.6.2.js"></script>
    <script
        src="https://ajax.aspnetcdn.com/ajax/jquery.validate/1.8.1/jquery.validate.js">
    </script>
    <script src="~/Scripts/jquery.validate.unobtrusive.js"></script>
</head>
<body>
  <h1>Validation Example with Client Validation</h1>
  <p>This example page asks the user to enter information about some classes at school.</p>
  <form method="post">
    @Html.ValidationSummary()
    <div>
      <label for="coursename">Course name: </label>
      <input type="text"
         name="coursename"
         value="@Request["coursename"]"
         @Validation.For("coursename")
      />
```

```
      @Html.ValidationMessage("coursename")
    </div>

    <div>
      <label for="credits">Credits: </label>
      <input type="text"
         name="credits"
         value="@Request["credits"]"
         @Validation.For("credits")
      />
      @Html.ValidationMessage("credits")
    </div>

    <div>
      <label for="startDate">Start date: </label>
      <input type="text"
         name="startDate"
         value="@Request["startDate"]"
         @Validation.For("startDate")
      />
      @Html.ValidationMessage("startDate")
    </div>

   <div>
      <input type="submit" value="Submit" class="submit" />
    </div>

    <div>
      @if(IsPost){
        <p>@Html.Raw(message)</p>
      }
    </div>
  </form>
</body>
</html>
```

Not all validation checks run on the client. In particular, data-type validation (integer, date, and so on) don't run on the client. The following checks work on both the client and server:

- `Required`
- `Range(minValue, maxValue)`
- `StringLength(maxLength[, minLength])`
- `Regex(pattern)`
- `EqualsTo(otherField)`

In this example, the test for a valid date won't work in client code. However, the test will be performed in server code.

Formatting Validation Errors

You can control how validation errors are displayed by defining CSS classes that have the following reserved names:

- `field-validation-error`. Defines the output of the `Html.ValidationMessage` method when it's displaying an error.
- `field-validation-valid`. Defines the output of the `Html.ValidationMessage` method when there is no error.
- `input-validation-error`. Defines how `<input>` elements are rendered when there's an error. (For example, you can use this class to set the background color of an <input> element to a different color if its value is invalid.) This CSS class is used only during client validation (in ASP.NET Web Pages 2).
- `input-validation-valid`. Defines the appearance of `<input>` elements when there is no error.

- `validation-summary-errors`. Defines the output of the `Html.ValidationSummary` method it's displaying a list of errors.
- `validation-summary-valid`. Defines the output of the `Html.ValidationSummary` method when there is no error.

The following `<style>` block shows rules for error conditions.

```
<style>
.validation-summary-errors {
  border:2px solid red;
  color:red;
  font-weight:bold;
  margin:6px;
  width:30%;
}

.field-validation-error{
  color:red;
   font-weight:bold;
   background-color:yellow;
}

.input-validation-error{
  color:red;
  font-weight:bold;
  background-color:pink;
}
</style>
```

If you include this style block in the example pages from earlier in the article, the error display will look like the following illustration:

> **NOTE**
> If you're not using client validation in ASP.NET Web Pages 2, the CSS classes for the `<input>` elements (`input-validation-error` and `input-validation-valid` don't have any effect.

Static and Dynamic Error Display

The CSS rules come in pairs, such as `validation-summary-errors` and `validation-summary-valid`. These pairs let you define rules for both conditions: an error condition and a "normal" (non-error) condition. It's important to understand that the markup for the error display is always rendered, even if there are no errors. For example, if a page has an `Html.ValidationSummary` method in the markup, the page source will contain the following markup even when the page is requested for the first time:

```
<div class="validation-summary-valid" data-valmsg-summary="true"><ul></ul></div>
```

In other words, the `Html.ValidationSummary` method always renders a `<div>` element and a list, even if the error

list is empty. Similarly, the `Html.ValidationMessage` method always renders a `<span>` element as a placeholder for an individual field error, even if there is no error.

In some situations, displaying an error message can cause the page to reflow and can cause elements on the page to move around. The CSS rules that end in `-valid` let you define a layout that can help prevent this problem. For example, you can define `field-validation-error` and `field-validation-valid` to both have the same fixed size. That way, the display area for the field is static and won't change the page flow if an error message is displayed.

Validating Data That Doesn't Come Directly from Users

Sometimes you have to validate information that doesn't come directly from an HTML form. A typical example is a page where a value is passed in a query string, as in the following example:

`http://server/myapp/EditClassInformation?classid=1022`

In this case, you want to make sure that the value that's passed to the page (here, 1022 for the value of `classid`) is valid. You can't directly use the `Validation` helper to perform this validation. However, you can use other features of the validation system, like the ability to display validation error messages.

> **NOTE**
>
> **Important** Always validate values that you get from *any* source, including form-field values, query-string values, and cookie values. It's easy for people to change these values (perhaps for malicious purposes). So you must check these values in order to protect your application.

The following example shows how you might validate a value that's passed in a query string. The code tests that the value is not empty and that it's an integer.

```
if(!IsPost){
    if(!Request.QueryString["classid"].IsEmpty() && Request.QueryString["classid"].IsInt()) {
        // Process the value
    }
    else{
        Validation.AddFormError("No class was selected.");
    }
}
```

Notice that the test is performed when the request is not a form submission (`if(!IsPost)`). This test would pass the first time that the page is requested, but not when the request is a form submission.

To display this error, you can add the error to the list of validation errors by calling `Validation.AddFormError("message")`. If the page contains a call to the `Html.ValidationSummary` method, the error is displayed there, just like a user-input validation error.

Working with HTML Forms in ASP.NET Web Pages Sites

Creating a Consistent Layout in ASP.NET Web Pages (Razor) Sites

2/20/2020 • 14 minutes to read • Edit Online

by Tom FitzMacken

This article explains how you can use layout pages in an ASP.NET Web Pages (Razor) website to create reusable blocks of content (like headers and footers) and to create a consistent look for all the pages in the site.

What you'll learn:

- How to create reusable blocks of content like headers and footers.
- How to create a consistent look for all the pages in your site using a layout.
- How to pass data at run time to a layout page.

These are the ASP.NET features introduced in the article:

- Content blocks, which are files that contain HTML-formatted content to be inserted in multiple pages.
- Layout pages, which are pages that contain HTML-formatted content that can be shared by pages on the website.
- The `RenderPage`, `RenderBody`, and `RenderSection` methods, which tell ASP.NET where to insert page elements.
- The `PageData` dictionary that lets you share data between content blocks and layout pages.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

About Layout Pages

Many websites have content that's displayed on every page, like a header and footer, or a box that tells users that they're logged in. ASP.NET lets you create a separate file with a content block that can contain text, markup, and code, just like a regular web page. You can then insert the content block in other pages on the site where you want the information to appear. That way you don't have to copy and paste the same content into every page. Creating common content like this also makes it easier to update your site. If you need to change the content, you can just update a single file, and the changes are then reflected everywhere the content has been inserted.

The following diagram shows how content blocks work. When a browser requests a page from the web server, ASP.NET inserts the content blocks at the point where the `RenderPage` method is called in the main page. The finished (merged) page is then sent to the browser.

In this procedure, you'll create a page that references two content blocks (a header and a footer) that are located in separate files. You can use these same content blocks in any page in your site. When you're done, you'll get a page like this:

1. In the root folder of your website, create a file named *Index.cshtml*.

2. Replace the existing markup with the following:

```
<!DOCTYPE html>
<html>
  <head>
    <title>Main Page</title>
  </head>
  <body>

    <h1>Index Page Content</h1>
    <p>This is the content of the main page.</p>

  </body>
</html>
```

3. In the root folder, create a folder named *Shared*.

> **NOTE**
>
> It's common practice to store files that are shared among web pages in a folder named *Shared*.

4. In the *Shared* folder, create a file named *_Header.cshtml*.

5. Replace any existing content with the following:

```
<div class="header">This is header text.</div>
```

Notice that the file name is *_Header.cshtml*, with an underscore (_) as a prefix. ASP.NET won't send a page to the browser if its name starts with an underscore. This prevents people from requesting (inadvertently or otherwise) these pages directly. It's a good idea to use an underscore to name pages that have content blocks in them, because you don't really want users to be able to request these pages — they exist strictly to be inserted into other pages.

6. In the *Shared* folder, create a file named *_Footer.cshtml* and replace the content with the following:

```
<div class="footer">&copy; 2012 Contoso Pharmaceuticals. All rights reserved.
</div>
```

7. In the *Index.cshtml* page, add two calls to the `RenderPage` method, as shown here:

```
<!DOCTYPE html>
<html>
  <head>
    <title>Main Page</title>
  </head>
  <body>

    @RenderPage("~/Shared/_Header.cshtml")

    <h1>Index Page Content</h1>
    <p>This is the content of the main page.</p>

    @RenderPage("~/Shared/_Footer.cshtml")

  </body>
</html>
```

This shows how to insert a content block into a web page. You call the `RenderPage` method and pass it the name of the file whose contents you want to insert at that point. Here, you're inserting the contents of the *_Header.cshtml* and *_Footer.cshtml* files into the *Index.cshtml* file.

8. Run the *Index.cshtml* page in a browser. (In WebMatrix, in the **Files** workspace, right-click the file and then select **Launch in browser**.)

9. In the browser, view the page source. (For example, in Internet Explorer, right-click the page and then click **View Source**.)

   This lets you see the web page markup that's sent to the browser, which combines the index page markup with the content blocks. The following example shows the page source that's rendered for *Index.cshtml*. The calls to `RenderPage` that you inserted into *Index.cshtml* have been replaced with the actual contents of the header and footer files.

```
<!DOCTYPE html>
<html>
  <head>
    <title>Main Page</title>
  </head>
  <body>

  <div class="header">
    This is header text.
  </div>

    <h1>Index Page Content</h1>
    <p>This is the content of the main page.</p>

  <div class="footer">
    &copy; 2012 Contoso Pharmaceuticals. All rights reserved.
  </div>

  </body>
</html>
```

Creating a Consistent Look Using Layout Pages

So far you've seen that it's easy to include the same content on multiple pages. A more structured approach to creating a consistent look for a site is to use layout pages. A layout page defines the structure of a web page, but doesn't contain any actual content. After you've created a layout page, you can create web pages that contain the content and then link them to the layout page. When these pages are displayed, they'll be formatted according to the layout page. (In this sense, a layout page acts as a kind of template for content that's defined in other pages.)

The layout page is just like any HTML page, except that it contains a call to the `RenderBody` method. The position of the `RenderBody` method in the layout page determines where the information from the content page will be included.

The following diagram shows how content pages and layout pages are combined at run time to produce the finished web page. The browser requests a content page. The content page has code in it that specifies the layout page to use for the page's structure. In the layout page, the content is inserted at the point where the `RenderBody` method is called. Content blocks can also be inserted into the layout page by calling the `RenderPage` method, the way you did in the previous section. When the web page is complete, it's sent to the browser.

The following procedure shows how to create a layout page and link content pages to it.

1. In the *Shared* folder of your website, create a file named *_Layout1.cshtml*.

2. Replace any existing content with the following:

```
<!DOCTYPE html>
<html>
  <head>
    <title>Structured Content </title>
    <link href="~/Styles/Site.css" rel="stylesheet" type="text/css" />
  </head>
  <body>
    @RenderPage("~/Shared/_Header2.cshtml")
    <div id="main">
      @RenderBody()
    </div>
    <div id="footer">
      &copy; 2012 Contoso Pharmaceuticals. All rights reserved.
    </div>
  </body>
</html>
```

You use the `RenderPage` method in a layout page to insert content blocks. A layout page can contain only one call to the `RenderBody` method.

3. In the *Shared* folder, create a file named *_Header2.cshtml* and replace any existing content with the following:

```
<div id="header">Creating a Consistent Look</div>
```

4. In the root folder, create a new folder and name it *Styles*.

5. In the *Styles* folder, create a file named *Site.css* and add the following style definitions:

```
h1 {
    border-bottom: 3px solid #cc9900;
    font: 2.75em/1.75em Georgia, serif;
    color: #996600;
}

ul {
    list-style-type: none;
}

body {
    margin: 0;
    padding: 1em;
    background-color: #ffffff;
    font: 75%/1.75em "Trebuchet MS", Verdana, sans-serif;
    color: #006600;
}

#list {
    margin: 1em 0 7em -3em;
    padding: 1em 0 0 0;
    background-color: #ffffff;
    color: #996600;
    width: 25%;
    float: left;
}

#header, #footer {
    margin: 0;
    padding: 0;
    color: #996600;
}
```

These style definitions are here only to show how style sheets can be used with layout pages. If you want, you can define your own styles for these elements.

6. In the root folder, create a file named *Content1.cshtml* and replace any existing content with the following:

```
@{
    Layout = "~/Shared/_Layout1.cshtml";
}

<h1> Structured Content </h1>
<p>Lorem ipsum dolor sit amet, consectetur adipisicing elit,
sed do eiusmod tempor incididunt ut labore et dolore magna aliqua.
Ut enim ad minim veniam, quis nostrud exercitation ullamco laboris
nisi ut aliquip ex ea commodo consequat. Duis aute irure dolor in
reprehenderit in voluptate velit esse cillum dolore eu fugiat nulla
pariatur. Excepteur sint occaecat cupidatat non proident, sunt in
culpa qui officia deserunt mollit anim id est laborum.</p>
```

This is a page that will use a layout page. The code block at the top of the page indicates which layout page to use to format this content.

7. Run *Content1.cshtml* in a browser. The rendered page uses the format and style sheet defined in *_Layout1.cshtml* and the text (content) defined in *Content1.cshtml*.

You can repeat step 6 to create additional content pages that can then share the same layout page.

> **NOTE**
> You can set up your site so that you can automatically use the same layout page for all the content pages in a folder. For details, see Customizing Site-Wide Behavior for ASP.NET Web Pages.

Designing Layout Pages That Have Multiple Content Sections

A content page can have multiple sections, which is useful if you want to use layouts that have multiple areas with replaceable content. In the content page, you give each section a unique name. (The default section is left unnamed.) In the layout page, you add a `RenderBody` method to specify where the unnamed (default) section should appear. You then add separate `RenderSection` methods in order to render named sections individually.

The following diagram shows how ASP.NET handles content that's divided into multiple sections. Each named section is contained in a section block in the content page. (They're named `Header` and `List` in the example.) The framework inserts content section into the layout page at the point where the `RenderSection` method is called. The unnamed (default) section is inserted at the point where the `RenderBody` method is called, as you saw earlier.

This procedure shows how to create a content page that has multiple content sections and how to render it using a layout page that supports multiple content sections.

1. In the *Shared* folder, create a file named *_Layout2.cshtml*.

2. Replace any existing content with the following:

```
<!DOCTYPE html>
<html>
  <head>
    <title>Multisection Content</title>
    <link href="~/Styles/Site.css" rel="stylesheet" type="text/css" />
  </head>
  <body>
    <div id="header">
      @RenderSection("header")
    </div>
    <div id="list">
      @RenderSection("list")
    </div>
    <div id="main">
      @RenderBody()
    </div>
    <div id="footer">
      &copy; 2012 Contoso Pharmaceuticals. All rights reserved.
    </div>
  </body>
</html>
```

   You use the `RenderSection` method to render both the header and list sections.

3. In the root folder, create a file named *Content2.cshtml* and replace any existing content with the following:

```
@{
    Layout = "~/Shared/_Layout2.cshtml";
}

@section header {
    <div id="header">
        Creating a Consistent Look
    </div>
}

@section list {
    <ul>
        <li>Lorem</li>
        <li>Ipsum</li>
        <li>Dolor</li>
        <li>Consecte</li>
        <li>Eiusmod</li>
        <li>Tempor</li>
        <li>Incididu</li>
    </ul>
}

<h1>Multisection Content</h1>
<p>Lorem ipsum dolor sit amet, consectetur adipisicing elit,
sed do eiusmod tempor incididunt ut labore et dolore magna aliqua.
Ut enim ad minim veniam, quis nostrud exercitation ullamco laboris
nisi ut aliquip ex ea commodo consequat. Duis aute irure dolor in
reprehenderit in voluptate velit esse cillum dolore eu fugiat nulla
pariatur. Excepteur sint occaecat cupidatat non proident, sunt in
culpa qui officia deserunt mollit anim id est laborum.</p>
```

This content page contains a code block at the top of the page. Each named section is contained in a section block. The rest of the page contains the default (unnamed) content section.

4. Run *Content2.cshtml* in a browser.

Making Content Sections Optional

Normally, the sections that you create in a content page have to match sections that are defined in the layout page. You can get errors if any of the following occur:

- The content page contains a section that has no corresponding section in the layout page.
- The layout page contains a section for which there's no content.
- The layout page includes method calls that try to render the same section more than once.

However, you can override this behavior for a named section by declaring the section to be optional in the layout page. This lets you define multiple content pages that can share a layout page but that might or might not have content for a specific section.

1. Open *Content2.cshtml* and remove the following section:

```
@section header {
  <div id="header">
    Creating a Consistent Look
  </div>
}
```

2. Save the page and then run it in a browser. An error message is displayed, because the content page doesn't provide content for a section defined in the layout page, namely the header section.

3. In the *Shared* folder, open the *_Layout2.cshtml* page and replace this line:

```
@RenderSection("header")
```

with the following code:

```
@RenderSection("header", required: false)
```

As an alternative, you could replace the previous line of code with the following code block, which produces the same results:

```
@if (IsSectionDefined("header")) {
    @RenderSection("header")
}
```

4. Run the *Content2.cshtml* page in a browser again. (If you still have this page open in the browser, you can just refresh it.) This time the page is displayed with no error, even though it has no header.

Passing Data to Layout Pages

You might have data defined in the content page that you need to refer to in a layout page. If so, you need to pass the data from the content page to the layout page. For example, you might want to display the login status of a user, or you might want to show or hide content areas based on user input.

To pass data from a content page to a layout page, you can put values into the `PageData` property of the content page. The `PageData` property is a collection of name/value pairs that hold the data that you want to pass between pages. In the layout page, you can then read values out of the `PageData` property.

Here's another diagram. This one shows how ASP.NET can use the `PageData` property to pass values from a content page to the layout page. When ASP.NET begins building the web page, it creates the `PageData` collection. In the content page, you write code to put data in the `PageData` collection. Values in the `PageData` collection can also be accessed by other sections in the content page or by additional content blocks.

The following procedure shows how to pass data from a content page to a layout page. When the page runs, it displays a button that lets the user hide or show a list that's defined in the layout page. When users click the button, it sets a true/false (Boolean) value in the `PageData` property. The layout page reads that value, and if it's false, hides the list. The value is also used in the content page to determine whether to display the **Hide List** button or the **Show List** button.

1. In the root folder, create a file named *Content3.cshtml* and replace any existing content with the following:

```
@{
    Layout = "~/Shared/_Layout3.cshtml";

    PageData["Title"] = "Passing Data";
    PageData["ShowList"] = true;

    if (IsPost) {
        if (Request.Form["list"] == "off") {
            PageData["ShowList"] = false;
        }
    }
}

@section header {
  <div id="header">
    Creating a Consistent Look
  </div>
}

<h1>@PageData["Title"]</h1>
<p>Lorem ipsum dolor sit amet, consectetur adipisicing elit,
sed do eiusmod tempor incididunt ut labore et dolore magna aliqua.
Ut enim ad minim veniam, quis nostrud exercitation ullamco laboris
nisi ut aliquip ex ea commodo consequat. Duis aute irure dolor in
reprehenderit in voluptate velit esse cillum dolore eu fugiat nulla
pariatur. Excepteur sint occaecat cupidatat non proident, sunt in
culpa qui officia deserunt mollit anim id est laborum.</p>

@if (PageData["ShowList"] == true) {
    <form method="post" action="">
      <input type="hidden" name="list" value="off" />
      <input type="submit" value="Hide List" />
    </form>
}
else {
    <form method="post" action="">
      <input type="hidden" name="list" value="on" />
      <input type="submit" value="Show List" />
    </form>
}
```

   The code stores two pieces of data in the `PageData` property — the title of the web page and true or false to specify whether to display a list.

   Notice that ASP.NET lets you put HTML markup into the page conditionally using a code block. For example, the `if/else` block in the body of the page determines which form to display depending on whether `PageData["ShowList"]` is set to true.

2. In the *Shared* folder, create a file named *_Layout3.cshtml* and replace any existing content with the following:

```
<!DOCTYPE html>
<html>
  <head>
    <title>@PageData["Title"]</title>
    <link href="~/Styles/Site.css" rel="stylesheet" type="text/css" />
  </head>
  <body>
    <div id="header">
      @RenderSection("header")
    </div>
      @if (PageData["ShowList"] == true) {
          <div id="list">
            @RenderPage("~/Shared/_List.cshtml")
          </div>
      }
    <div id="main">
      @RenderBody()
    </div>
    <div id="footer">
      <p>&copy; 2012 Contoso Pharmaceuticals. All rights reserved.</p>
    </div>
  </body>
</html>
```

The layout page includes an expression in the `<title>` element that gets the title value from the `PageData` property. It also uses the `ShowList` value of the `PageData` property to determine whether to display the list content block.

3. In the *Shared* folder, create a file named *_List.cshtml* and replace any existing content with the following:

```
<ul>
  <li>Lorem</li>
  <li>Ipsum</li>
  <li>Dolor</li>
  <li>Consecte</li>
  <li>Eiusmod</li>
  <li>Tempor</li>
  <li>Incididu</li>
</ul>
```

4. Run the *Content3.cshtml* page in a browser. The page is displayed with the list visible on the left side of the page and a **Hide List** button at the bottom.

5. Click **Hide List**. The list disappears and the button changes to **Show List**.

6. Click the **Show List** button, and the list is displayed again.

Customizing Site-Wide Behavior for ASP.NET Web Pages

Customizing Site-Wide Behavior for ASP.NET Web Pages (Razor) Sites

2/20/2020 • 12 minutes to read • Edit Online

by Tom FitzMacken

This article explains how to make site-side settings for pages in an ASP.NET Web Pages (Razor) website.

What you'll learn:

- How to run code that lets you set values (global values or helper settings) for all pages in a site.
- How to run code that lets you set values for all pages in a folder.
- How to run code before and after a page loads.
- How to send errors to a central error page.
- How to add authentication to all pages in a folder.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- WebMatrix 3
- ASP.NET Web Helpers Library (NuGet package)

This tutorial also works with ASP.NET Web Pages 3 and Visual Studio 2013 (or Visual Studio Express 2013 for Web), except you cannot use the ASP.NET Web Helpers Library.

Adding Website Startup Code for ASP.NET Web Pages

For much of the code that you write in ASP.NET Web Pages, an individual page can contain all the code that's required for that page. For example, if a page sends an email message, it's possible to put all the code for that operation in a single page. This can include the code to initialize the settings for sending email (that is, for the SMTP server) and for sending the email message.

However, in some situations, you might want to run some code before any page on the site runs. This is useful for setting values that can be used anywhere in the site (referred to as *global values*.) For example, some helpers require you to provide values like email settings or account keys. It can be handy to keep these settings in global values.

You can do this by creating a page named *_AppStart.cshtml* in the root of the site. If this page exists, it runs the first time any page in the site is requested. Therefore, it's a good place to run code to set global values. (Because *_AppStart.cshtml* has an underscore prefix, ASP.NET won't send the page to a browser even if users request it directly.)

The following diagram shows how the *_AppStart.cshtml* page works. When a request comes in for a page, and if this is the first request for any page in the site, ASP.NET first checks whether a *_AppStart.cshtml* page exists. If so, any code in the *_AppStart.cshtml* page runs, and then the requested page runs.

Setting Global Values for Your Website

1. In the root folder of a WebMatrix website, create a file named *_AppStart.cshtml*. The file must be in the root of the site.

2. Replace the existing content with the following:

```
@{
  AppState["customAppName"] = "Application Name";
}
```

   This code stores a value in the `AppState` dictionary, which is automatically available to all pages in the site. Notice that the *_AppStart.cshtml* file does not have any markup in it. The page will run the code and then redirect to the page that was originally requested.

   > **NOTE**
   > Be careful when you put code in the *_AppStart.cshtml* file. If any errors occur in code in the *_AppStart.cshtml* file, the website won't start.

3. In the root folder, create a new page named *AppName.cshtml*.

4. Replace the default markup and code with the following:

```
<!DOCTYPE html>
<html>
    <head>
        <title>Show Application Name</title>
    </head>
    <body>
        <h1>@AppState["customAppName"]</h1>
    </body>
</html>
```

   This code extracts the value from the `AppState` object that you set in the *_AppStart.cshtml* page.

5. Run the *AppName.cshtml* page in a browser. (Make sure the page is selected in the **Files** workspace before you run it.) The page displays the global value.

Setting Values for Helpers

A good use for the *_AppStart.cshtml* file is to set values for helpers that you use in your site and that have to be initialized. Typical examples are email settings for the `WebMail` helper and the private and public keys for the `ReCaptcha` helper. In cases like these, you can set the values once in the *_AppStart.cshtml* and then they're already set for all the pages in your site.

This procedure shows you how to set `WebMail` settings globally. (For more information about using the `WebMail` helper, see Adding Email to an ASP.NET Web Pages Site.)

1. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already added it.

2. If you don't already have a *_AppStart.cshtml* file, in the root folder of a website create a file named *_AppStart.cshtml*.

3. Add the following `WebMail` settings to the *_AppStart.cshtml* file:

```
@{
     // Initialize WebMail helper
     WebMail.SmtpServer = "your-SMTP-host";
     WebMail.SmtpPort = 25;
     WebMail.UserName = "your-user-name-here";
     WebMail.Password = "your-account-password";
     WebMail.From = "your-email-address-here";
}
```

   Modify the following email related settings in the code:

   - Set `your-SMTP-host` to the name of the SMTP server that you have access to.
   - Set `your-user-name-here` to the user name for your SMTP server account.
   - Set `your-account-password` to the password for your SMTP server account.
   - Set `your-email-address-here` to your own email address. This is the email address that the message is sent from. (Some email providers don't let you specify a different `From` address and will use your user name as the `From` address.)

     For more information about SMTP settings, see Configuring Email Settings in the article Sending Email from an ASP.NET Web Pages (Razor) Site and Issues with Sending Email in the ASP.NET Web Pages (Razor) Troubleshooting Guide.

4. Save the *_AppStart.cshtml* file and close it.

5. In the root folder of a website, create new page named *TestEmail.cshtml*.

6. Replace the existing content with the following:

```
@{
    var message = "";
    try{
        if(IsPost){
            WebMail.Send(
                to: Request.Form["emailAddress"],
                subject: Request.Form["emailSubject"],
                body:Request.Form["emailBody"]
           );
           message = "Email sent!";
        }
    }
    catch(Exception ex){
        message = "Email could not be sent!";
    }
}
<!DOCTYPE html>
<html lang="en">
  <head>
     <meta charset="utf-8" />
     <title>Test Email</title>
  </head>
  <body>
    <h1>Test Email</h1>
    <form method="post">
      <p>
        <label for="emailAddress">Email address:</label>
        <input type="text" name="emailAddress" />
      </p>
      <p>
        <label for="emailSubject">Subject:</label>
        <input type="text" name="emailSubject" />
      </p>
      <p>
        <label for="emailBody">Text to send:</label><br/>
        <textarea name="emailBody" rows="6"></textarea>
      </p>
    <p><input type="submit" value="Send!" /></p>
    @if(IsPost){
        <p>@message</p>
    }
    </form>
  </body>
</html>
```

7. Run the *TestEmail.cshtml* page in a browser.

8. Fill in the fields to send yourself an email message and then click **Send**.

9. Check your email to make sure you've gotten the message.

The important part of this example is that the settings that you don't usually change — like the name of your SMTP server and your email credentials — are set in the *_AppStart.cshtml* file. That way you don't need to set them again in each page where you send email. (Although if for some reason you need to change those settings, you can set them individually in a page.) In the page, you only set the values that typically change each time, like the recipient and the body of the email message.

Running Code Before and After Files in a Folder

Just like you can use *_AppStart.cshtml* to write code before pages in the site run, you can write code that runs before (and after) any page in a particular folder run. This is useful for things like setting the same layout page for all the pages in a folder, or for checking that a user is logged in before running a page in the folder.

For pages in particular folders, you can create code in a file named *_PageStart.cshtml*. The following diagram shows how the *_PageStart.cshtml* page works. When a request comes in for a page, ASP.NET first checks for a *_AppStart.cshtml* page and runs that. Then ASP.NET checks whether there's a *_PageStart.cshtml* page, and if so, runs that. It then runs the requested page.

Inside the *_PageStart.cshtml* page, you can specify where during processing you want the requested page to run by including a `RunPage` method. This lets you run code before the requested page runs and then again after it. If you don't include `RunPage`, all the code in *_PageStart.cshtml* runs, and then the requested page runs automatically.

ASP.NET lets you create a hierarchy of *_PageStart.cshtml* files. You can put a *_PageStart.cshtml* file in the root of the site and in any subfolder. When a page is requested, the *_PageStart.cshtml* file at the top-most level (nearest to the site root) runs, followed by the *_PageStart.cshtml* file in the next subfolder, and so on down the subfolder structure until the request reaches the folder that contains the requested page. After all the applicable *_PageStart.cshtml* files have run, the requested page runs.

For example, you might have the following combination of *_PageStart.cshtml* files and *Default.cshtml* file:

```
@* ~/_PageStart.cshtml *@
@{
  PageData["Color1"] = "Red";
  PageData["Color2"] = "Blue";
}
```

```
@* ~/myfolder/_PageStart.cshtml *@
@{
  PageData["Color2"] = "Yellow";
  PageData["Color3"] = "Green";
}
```

```
@* ~/myfolder/default.cshtml *@
@PageData["Color1"]
<br/>
@PageData["Color2"]
<br/>
@PageData["Color3"]
```

When you run */myfolder/default.cshtml*, you'll see the following:

```
Red

Yellow

Green
```

Running Initialization Code for All Pages in a Folder

A good use for *_PageStart.cshtml* files is to initialize the same layout page for all files in a single folder.

1. In the root folder, create a new folder named *InitPages*.
2. In the *InitPages* folder of your website, create a file named *_PageStart.cshtml* and replace the default markup and code with the following:

```
@{
    // Sets the layout page for all pages in the folder.
    Layout = "~/Shared/_Layout1.cshtml";

    // Sets a variable available to all pages in the folder.
    PageData["MyBackground"] = "Yellow";
}
```

3. In the root of the website, create a folder named *Shared*.
4. In the *Shared* folder, create a file named *_Layout1.cshtml* and replace the default markup and code with the following:

```
@{
  var backgroundColor = PageData["MyBackground"];
}
<!DOCTYPE html>
<html>
<head>
  <title>Page Title</title>
  <link type="text/css" href="/Styles/Site.css" rel="stylesheet" />
</head>
<body>
  <div id="header">
    Using the _PageStart.cshtml file
  </div>
  <div id="main" style="background-color:@backgroundColor">
    @RenderBody()
  </div>
<div id="footer">
  &copy; 2012 Contoso. All rights reserved
</div>
</body>
</html>
```

5. In the *InitPages* folder, create a file named *Content1.cshtml* and replace the existing content with the following:

```
<p>This is content page 1.</p>
```

6. In the *InitPages* folder, create another file named *Content2.cshtml* and replace the default markup with the following:

```
<p>This is content page 2.</p>
```

7. Run *Content1.cshtml* in a browser.

   When the *Content1.cshtml* page runs, the *_PageStart.cshtml* file sets `Layout` and also sets `PageData["MyBackground"]` to a color. In *Content1.cshtml*, the layout and color are applied.

8. Display *Content2.cshtml* in a browser.

   The layout is the same, because both pages use the same layout page and color as initialized in *_PageStart.cshtml*.

Using _PageStart.cshtml to Handle Errors

Another good use for the *_PageStart.cshtml* file is to create a way to handle programming errors (exceptions) that might occur in any *.cshtml* page in a folder. This example shows you one way to do this.

1. In the root folder, create a folder named *InitCatch*.

2. In the *InitCatch* folder of your website, create a file named *_PageStart.cshtml* and replace the existing markup and code with the following:

```
@{
    try
    {
        RunPage();
    }
    catch (Exception ex)
    {
        Response.Redirect("~/Error.cshtml?source=" +
            HttpUtility.UrlEncode(Request.AppRelativeCurrentExecutionFilePath));
    }
}
```

   In this code, you try running the requested page explicitly by calling the `RunPage` method inside a `try` block. If any programming errors occur in the requested page, the code inside the `catch` block runs. In this case, the code redirects to a page (*Error.cshtml*) and passes the name of the file that experienced the error as part of the URL. (You'll create the page shortly.)

3. In the *InitCatch* folder of your website, create a file named *Exception.cshtml* and replace the existing markup and code with the following:

```
@{
    var db = Database.Open("invalidDatabaseFile");
}
```

   For purposes of this example, what you're doing in this page is deliberately creating an error by trying to open a database file that doesn't exist.

4. In the root folder, create a file named *Error.cshtml* and replace the existing markup and code with the

following:

```
<!DOCTYPE html>
<html>
    <head>
        <title>Error Page</title>
    </head>
    <body>
<h1>Error report</h1>
<p>An error occurred while running the following file: @Request["source"]</p>
    </body>
</html>
```

In this page, the expression `@Request["source"]` gets the value out of the URL and displays it.

5. In the toolbar, click **Save**.

6. Run *Exception.cshtml* in a browser.

Because an error occurs in *Exception.cshtml*, the *_PageStart.cshtml* page redirects to the *Error.cshtml* file, which displays the message.

For more information about exceptions, see Introduction to ASP.NET Web Pages Programming Using the Razor Syntax.

Using _PageStart.cshtml to Restrict Folder Access

You can also use the *_PageStart.cshtml* file to restrict access to all the files in a folder.

1. In WebMatrix, create a new website using the **Site From Template** option.

2. From the available templates, select **Starter Site**.

3. In the root folder, create a folder named *AuthenticatedContent*.

4. In the *AuthenticatedContent* folder, create a file named *_PageStart.cshtml* and replace the existing markup and code with the following:

```
@{
    Response.CacheControl = "no-cache";
    if (!WebSecurity.IsAuthenticated) {
        var returnUrl = "~/Account/Login?ReturnUrl=" + Request.Url.LocalPath;
        Response.Redirect(returnUrl);
    }
}
```

The code starts by preventing all files in the folder from being cached. (This is required for scenarios like public computers, where you don't want one user's cached pages to be available to the next user.) Next, the code determines whether the user has signed in to the site before they can view any of the pages in the folder. If the user is not signed in, the code redirects to the login page. The login page can return the user to the page that was originally requested if you include a query string value named `ReturnUrl`.

5. Create a new page in the *AuthenticatedContent* folder named *Page.cshtml*.

6. Replace the default markup with the following:

```
@{
    Layout = "~/_SiteLayout.cshtml";
    Page.Title = "Authenticated Content";
}
<!DOCTYPE html>
<html>
  <head>
    <meta charset="utf-8" />
  </head>
  <body>
    Thank you for authenticating!
  </body>
</html>
```

7. Run *Page.cshtml* in a browser. The code redirects you to a login page. You must register before logging in. After you've registered and logged in, you can navigate to the page and view its contents.

Introduction to ASP.NET Web Pages Programming Using the Razor Syntax

Working with Images in an ASP.NET Web Pages (Razor) Site

2/20/2020 • 15 minutes to read • Edit Online

by Tom FitzMacken

This article shows you how to add, display, and manipulate images (resize, flip, and add watermarks) in an ASP.NET Web Pages (Razor) website.

What you'll learn:

- How to add an image to a page dynamically.
- How to let users upload an image.
- How to resize an image.
- How to flip or rotate an image.
- How to add a watermark to an image.
- How to use an image as a watermark.

These are the ASP.NET programming features introduced in the article:

- The `WebImage` helper.
- The `Path` object, which provides methods that let you manipulate path and file names.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- WebMatrix 2

This tutorial also works with WebMatrix 3.

Adding an Image to a Web Page Dynamically

You can add images to your website and to individual pages while you're developing the website. You can also let users upload images, which might be useful for tasks like letting them add a profile photo.

If an image is already available on your site and you just want to display it on a page, you use an HTML `<img>` element like this:

```
<img src="images/Photo1.jpg" alt="Sample Photo" />
```

Sometimes, though, you need to be able to display images dynamically — that is, you don't know what image to display until the page is running.

The procedure in this section shows how to display an image on the fly where users specify the image file name from a list of image names. They select the name of the image from a drop-down list, and when they submit the page, the image they selected is displayed.

1. In WebMatrix, create a new website.
2. Add a new page named *DynamicImage.cshtml*.
3. In the root folder of the website, add a new folder and name it *images*.
4. Add four images to the *images* folder you just created. (Any images you have handy will do, but they should fit onto a page.) Rename the images *Photo1.jpg*, *Photo2.jpg*, *Photo3.jpg*, and *Photo4.jpg*. (You won't use *Photo4.jpg* in this procedure, but you'll use it later in the article.)
5. Verify that the four images are not marked as read-only.
6. Replace the existing content in the page with the following:

```
@{  var imagePath= "";
    if( Request["photoChoice"] != null){
        imagePath = @"images\" + Request["photoChoice"];
   }
}
<!DOCTYPE html>
<html>
<head>
  <title>Display Image on the Fly</title>
</head>
<body>
<h1>Displaying an Image On the Fly</h1>
<form method="post" action="">
    <div>
        I want to see:
        <select name="photoChoice">
            <option value="Photo1.jpg">Photo 1</option>
            <option value="Photo2.jpg">Photo 2</option>
            <option value="Photo3.jpg">Photo 3</option>
        </select>
         
        <input type="submit" value="Submit" />
    </div>
    <div style="padding:10px;">
        @if(imagePath != ""){
            <img src="@imagePath" alt="Sample Image" width="300px" />
        }
    </div>
</form>
</body>
</html>
```

The body of the page has a drop-down list (a `<select>` element) that's named `photoChoice`. The list has

three options, and the `value` attribute of each list option has the name of one of the images that you put in the *images* folder. Essentially, the list lets the user select a friendly name like "Photo 1", and it then passes the *.jpg* file name when the page is submitted.

In the code, you can get the user's selection (in other words, the image file name) from the list by reading `Request["photoChoice"]`. You first see if there's a selection at all. If there is, you construct a path for the image that consists of the name of the folder for the images and the user's image file name. (If you tried to construct a path but there was nothing in `Request["photoChoice"]`, you'd get an error.) This results in a relative path like this:

images/Photo1.jpg

The path is stored in variable named `imagePath` that you'll need later in the page.

In the body, there's also an `<img>` element that's used to display the image that the user picked. The `src` attribute isn't set to a file name or URL, like you'd do to display a static element. Instead, it's set to `@imagePath`, meaning that it gets its value from the path you set in code.

The first time that the page runs, though, there's no image to display, because the user hasn't selected anything. This would normally mean that the `src` attribute would be empty and the image would show up as a red "x" (or whatever the browser renders when it can't find an image). To prevent this, you put the `<img>` element in an `if` block that tests to see whether the `imagePath` variable has anything in it. If the user made a selection, `imagePath` contains the path. If the user didn't pick an image or if this is the first time the page is displayed, the `<img>` element isn't even rendered.

7. Save the file and run the page in a browser. (Make sure the page is selected in the **Files** workspace before you run it.)

8. Select an image from the drop-down list and then click **Sample Image**. Make sure that you see different images for different choices.

Uploading an Image

The previous example showed you how to display an image dynamically, but it worked only with images that were already on your website. This procedure shows how to let users upload an image, which is then displayed on the page. In ASP.NET, you can manipulate images on the fly using the `WebImage` helper, which has methods that let you create, manipulate, and save images. The `WebImage` helper supports all the common web image file types, including *.jpg*, *.png*, and *.bmp*. Throughout this article, you'll use *.jpg* images, but you can use any of the image types.

1. Add a new page and name it *UploadImage.cshtml*.

2. Replace the existing content in the page with the following:

```
@{  WebImage photo = null;
    var newFileName = "";
    var imagePath = "";

    if(IsPost){
        photo = WebImage.GetImageFromRequest();
        if(photo != null){
            newFileName = Guid.NewGuid().ToString() + "_" +
                Path.GetFileName(photo.FileName);
            imagePath = @"images\" + newFileName;

            photo.Save(@"~\" + imagePath);
        }
    }
}
<!DOCTYPE html>
<html>
<head>
  <title>Image Upload</title>
</head>
<body>
  <form action="" method="post" enctype="multipart/form-data">
    <fieldset>
      <legend> Upload Image </legend>
      <label for="Image">Image</label>
      <input type="file" name="Image" />
      <br/>
      <input type="submit" value="Upload" />
    </fieldset>
  </form>
  <h1>Uploaded Image</h1>
    @if(imagePath != ""){
    <div class="result">
        <img src="@imagePath" alt="image" />

    </div>
    }
</body>
</html>
```

The body of the text has an `<input type="file">` element, which lets users select a file to upload. When they click **Submit**, the file they picked is submitted along with the form.

To get the uploaded image, you use the `WebImage` helper, which has all sorts of useful methods for working with images. Specifically, you use `WebImage.GetImageFromRequest` to get the uploaded image (if any) and store it in a variable named `photo`.

A lot of the work in this example involves getting and setting file and path names. The issue is that you want to get the name (and just the name) of the image that the user uploaded, and then create a new path for where you're going to store the image. Because users could potentially upload multiple images that have the same name, you use a bit of extra code to create unique names and make sure that users don't overwrite existing pictures.

If an image actually has been uploaded (the test `if (photo != null)`), you get the image name from the image's `FileName` property. When the user uploads the image, `FileName` contains the user's original name, which includes the path from the user's computer. It might look like this:

C:\Users\Joe\Pictures\SamplePhoto1.jpg

You don't want all that path information, though — you just want the actual file name (*SamplePhoto1.jpg*).

You can strip out just the file from a path by using the `Path.GetFileName` method, like this:

```
Path.GetFileName(photo.FileName)
```

You then create a new unique file name by adding a GUID to the original name. (For more about GUIDs, see About GUIDs later in this article.) Then you construct a complete path that you can use to save the image. The save path is made up of the new file name, the folder (images), and the current website location.

> **NOTE**
> In order for your code to save files in the *images* folder, the application needs read-write permissions for that folder. On your development computer this is not typically an issue. However, when you publish your site to a hosting provider's web server, you might need to explicitly set those permissions. If you run this code on a hosting provider's server and get errors, check with the hosting provider to find out how to set those permissions.

Finally, you pass the save path to the `Save` method of the `WebImage` helper. This stores the uploaded image under its new name. The save method looks like this: `photo.Save(@"~\" + imagePath)`. The complete path is appended to `@"~\"`, which is the current website location. (For information about the `~` operator, see Introduction to ASP.NET Web Programming Using the Razor Syntax.)

As in the previous example, the body of the page contains an `<img>` element to display the image. If `imagePath` has been set, the `<img>` element is rendered and its `src` attribute is set to the `imagePath` value.

3. Run the page in a browser.
4. Upload an image and make sure it's displayed in the page.
5. In your site, open the *images* folder. You see that a new file has been added whose file name looks something like this::

   45ea4527-7ddd-4965-b9ca-c6444982b342_MyPhoto.png

   This is the image that you uploaded with a GUID prefixed to the name. (Your own file will have a different GUID and probably is named something different than *MyPhoto.png*.)

> **TIP**
>
> **About GUIDs**
> A GUID (globally-unique ID) is an identifier that's usually rendered in a format like this: `936DA01F-9ABD-4d9d-80C7-02AF85C822A8`. The numbers and letters (from A-F) differ for each GUID, but they all follow the pattern of using groups of 8-4-4-4-12 characters. (Technically, a GUID is a 16-byte/128-bit number.) When you need a GUID, you can call specialized code that generates a GUID for you. The idea behind GUIDs is that between the enormous size of the number (3.4×10^{38}) and the algorithm for generating it, the resulting number is virtually guaranteed to be one of a kind. GUIDs therefore are a good way to generate names for things when you must guarantee that you won't use the same name twice. The downside, of course, is that GUIDs aren't particularly user friendly, so they tend to be used when the name is used only in code.

Resizing an Image

If your website accepts images from a user, you might want to resize the images before you display or save them. You can again use the `WebImage` helper for this.

This procedure shows how to resize an uploaded image to create a thumbnail and then save the thumbnail and original image in the website. You display the thumbnail on the page and use a hyperlink to redirect users to the

full-sized image.

1. Add a new page named *Thumbnail.cshtml*.
2. In the *images* folder, create a subfolder named *thumbs*.
3. Replace the existing content in the page with the following:

```
@{
    WebImage photo = null;
    var newFileName = "";
    var imagePath = "";
    var imageThumbPath  = "";

    if(IsPost){
        photo = WebImage.GetImageFromRequest();
        if(photo != null){
             newFileName = Guid.NewGuid().ToString() + "_" +
                 Path.GetFileName(photo.FileName);
             imagePath = @"images\" + newFileName;
             photo.Save(@"~\" + imagePath);

            imageThumbPath = @"images\thumbs\" + newFileName;
            photo.Resize(width: 60, height: 60, preserveAspectRatio: true,
               preventEnlarge: true);
            photo.Save(@"~\" + imageThumbPath);        }
    }
}
<!DOCTYPE html>
<html>
<head>
  <title>Resizing Image</title>
</head>
<body>
<h1>Thumbnail Image</h1>
  <form action="" method="post" enctype="multipart/form-data">
    <fieldset>
      <legend> Creating Thumbnail Image </legend>
      <label for="Image">Image</label>
      <input type="file" name="Image" />
      <br/>
      <input type="submit" value="Submit" />
    </fieldset>
  </form>
    @if(imagePath != ""){
    <div class="result">
        <img src="@imageThumbPath" alt="Thumbnail image" />
        <a href="@Html.AttributeEncode(imagePath)" target="_Self">
            View full size
        </a>
    </div>

    }
</body>
</html>
```

This code is similar to the code from the previous example. The difference is that this code saves the image twice, once normally and once after you create a thumbnail copy of the image. First you get the uploaded image and save it in the *images* folder. You then construct a new path for the thumbnail image. To actually create the thumbnail, you call the `WebImage` helper's `Resize` method to create a 60-pixel by 60-pixel image. The example shows how you preserve the aspect ratio and how you can prevent the image from being enlarged (in case the new size would actually make the image larger). The resized image is then saved in the *thumbs* subfolder.

At the end of the markup, you use the same `<img>` element with the dynamic `src` attribute that you've seen in the previous examples to conditionally show the image. In this case, you display the thumbnail. You also use an `<a>` element to create a hyperlink to the big version of the image. As with the `src` attribute of the `<img>` element, you set the `href` attribute of the `<a>` element dynamically to whatever is in `imagePath`. To make sure that the path can work as a URL, you pass `imagePath` to the `Html.AttributeEncode` method, which converts reserved characters in the path to characters that are ok in a URL.

4. Run the page in a browser.
5. Upload a photo and verify that the thumbnail is shown.
6. Click the thumbnail to see the full-size image.
7. In the *images* and *images/thumbs*, note that new files have been added.

Rotating and Flipping an Image

The `WebImage` helper also lets you flip and rotate images. This procedure shows how to get an image from the server, flip the image upside down (vertically), save it, and then display the flipped image on the page. In this example, you're just using a file you already have on the server (*Photo2.jpg*). In a real application, you'd probably flip an image whose name you get dynamically, like you did in previous examples.

1. Add a new page named *FlipImage.cshtml*.
2. Replace the existing content in the page with the following:

```
@{  var imagePath= "";
    WebImage photo = new WebImage(@"~\Images\Photo2.jpg");
    if(photo != null){
        imagePath = @"images\Photo2.jpg";
        photo.FlipVertical();
        photo.Save(@"~\" + imagePath);
     }
}
<!DOCTYPE html>
<html>
<head>
  <title>Get Image From File</title>
  <meta http-equiv="content-type" content="text/html;charset=utf-8" />
</head>
<body>
<h1>Flip Image Vertically</h1>
@if(imagePath != ""){
  <div class="result">
    <img src="@imagePath" alt="Image" />
  </div>
}
</body>
</html>
```

The code uses the `WebImage` helper to get an image from the server. You create the path to the image using the same technique you used in earlier examples for saving images, and you pass that path when you create an image using `WebImage`:

```
WebImage photo = new WebImage(@"~\Images\Photo2.jpg");
```

If an image is found, you construct a new path and file name, like you did in earlier examples. To flip the image, you call the `FlipVertical` method, and then you save the image again.

The image is again displayed on the page by using the `<img>` element with the `src` attribute set to `imagePath`.

3. Run the page in a browser. The image for *Photo2.jpg* is shown upside down.
4. Refresh the page or request the page again to see the image is flipped right side up again.

To rotate an image, you use the same code, except that instead of calling the `FlipVertical` or `FlipHorizontal`, you call `RotateLeft` or `RotateRight`.

Adding a Watermark to an Image

When you add images to your website, you might want to add a watermark to the image before you save it or display it on a page. People often use watermarks to add copyright information to an image or to advertise their business name.

1. Add a new page named *Watermark.cshtml*.
2. Replace the existing content in the page with the following:

```
@{  var imagePath= "";
    WebImage photo = new WebImage(@"~\Images\Photo3.jpg");
    if(photo != null){
        imagePath = @"images\Photo3.jpg";
        photo.AddTextWatermark("My Watermark", fontColor:"Yellow", fontFamily:
            "Arial");
        photo.Save(@"~\" + imagePath);    }
}
<!DOCTYPE html>
<html>
<head>
  <title>Water Mark</title>
  <meta http-equiv="content-type" content="text/html;charset=utf-8" />
</head>
<body>
<h1>Adding a Watermark to an Image</h1>
@if(imagePath != ""){
  <div class="result">
    <img src="@imagePath" alt="Image" />
  </div>
}
</body>
</html>
```

This code is like the code in the *FlipImage.cshtml* page from earlier (although this time it uses the *Photo3.jpg* file). To add the watermark, you call the `WebImage` helper's `AddTextWatermark` method before you save the image. In the call to `AddTextWatermark`, you pass the text "My Watermark", set the font color to yellow, and set the font family to Arial. (Although it's not shown here, the `WebImage` helper also lets you specify opacity, font family and font size, and the position of the watermark text.) When you save the image it must not be read-only.

As you've seen before, the image is displayed on the page by using the `<img>` element with the src attribute set to `@imagePath`.

3. Run the page in a browser. Notice the text "My Watermark" at the bottom-right corner of the image.

Using an Image As a Watermark

Instead of using text for a watermark, you can use another image. People sometimes use images like a company logo as a watermark, or they use a watermark image instead of text for copyright information.

1. Add a new page named *ImageWatermark.cshtml*.
2. Add an image to the *images* folder that you can use as a logo, and rename the image *MyCompanyLogo.jpg*. This image should be an image that you can see clearly when it's set to 80 pixels wide and 20 pixels high.
3. Replace the existing content in the page with the following:

```
@{  var imagePath = "";
   WebImage WatermarkPhoto = new WebImage(@"~\" +
        @"\Images\MyCompanyLogo.jpg");
    WebImage photo = new WebImage(@"~\Images\Photo4.jpg");
    if(photo != null){
        imagePath = @"images\Photo4.jpg";
        photo.AddImageWatermark(WatermarkPhoto, width: 80, height: 20,
           horizontalAlign:"Center", verticalAlign:"Bottom",
           opacity:100,  padding:10);
      photo.Save(@"~\" + imagePath);
   }
}
<!DOCTYPE html>
<html>
<head>
  <title>Image Watermark</title>
  <meta http-equiv="content-type" content="text/html;charset=utf-8" />
</head>
<body>
  <h1>Using an Image as a Watermark</h1>
  @if(imagePath != ""){
    <div class="result">
      <img src="@imagePath" alt="Image" />
    </div>
  }
</body>
</html>
```

This is another variation on the code from earlier examples. In this case, you call `AddImageWatermark` to add the watermark image to the target image (*Photo3.jpg*) before you save the image. When you call `AddImageWatermark`, you set its width to 80 pixels and the height to 20 pixels. The *MyCompanyLogo.jpg* image is horizontally aligned in the center and vertically aligned at the bottom of the target image. The opacity is set to 100% and the padding is set to 10 pixels. If the watermark image is bigger than the target image, nothing will happen. If the watermark image is bigger than the target image and you set the padding for the image watermark to zero, the watermark is ignored.

As before, you display the image using the `<img>` element and a dynamic `src` attribute.

4. Run the page in a browser. Notice that the watermark image appears at the bottom of the main image.

Introduction to ASP.NET Web Pages Programming Using the Razor Syntax

Displaying Video in an ASP.NET Web Pages (Razor) Site

2/20/2020 • 7 minutes to read • Edit Online

by Tom FitzMacken

This article explains how to use a video (media) player in an ASP.NET Web Pages (Razor) website to let users view videos that are stored on the site. ASP.NET Web Pages with Razor syntax lets you play Flash (*.swf*), Media Player (*.wmv*), and Silverlight (*.xap*) videos.

What you'll learn:

- How to choose a video player.
- How to add video to a web page.
- How to set video player attributes.

These are the ASP.NET Razor pages features introduced in the article:

- The `Video` helper.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- WebMatrix 2

This tutorial also works with WebMatrix 3.

Introduction

You might want to display a video on your site. One way to do that is to link to a site that already has the video, like YouTube. If you want to embed a video from these sites directly in your own pages, you can usually get HTML markup from the site and then copy it into your page. For example, the following example shows how to embed a YouTube video:

```
<!DOCTYPE html>
<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title>Embedded Video Example</title>
    </head>
    <body>
        <h1>Embedded Video Example</h1>
        <p>The following video provides an introduction to WebMatrix:</p>
        <iframe width="560"
                height="315"
                src="http://www.youtube.com/embed/fxCEcPxUbYA"
                frameborder="0"
                allowfullscreen></iframe>
</body>
</html>
```

If you want to play a video that's on your own website (not on a public video-sharing site), you can't directly link to it using embedded markup like this. However, you can play videos from your site by using the `Video` helper, which

renders a media player directly in a page.

Choosing a Video Player

There are lots of formats for video files, and each format typically requires a different player and a different way to configure the player. In ASP.NET Razor pages, you can play a video in a web page using the `Video` helper. The `Video` helper simplifies the process of embedding videos in a web page because it automatically generates the `object` and `embed` HTML elements that are normally used to add video to the page.

The `Video` helper supports the following media players:

- Adobe Flash
- Windows MediaPlayer
- Microsoft Silverlight

The Flash Player

The `Flash` player of the `Video` helper let you play Flash videos (*.swf* files) in a web page. At a minimum, you have to provide a path to the video file. If you specify nothing but the path, the player uses default values that are set by the current version of Flash. Typical default settings are:

- The video is displayed using its default width and height and without a background color.
- The video plays automatically when the page loads.
- The video loops continuously until it's explicitly stopped.
- The video is scaled to show all of the video, rather than cropping the video to fit a specific size.
- The video plays in a window.

The MediaPlayer Player

The `MediaPlayer` player of the `Video` helper lets you play Windows Media videos (*.wmv* files), Windows Media audio (*.wma* files), and MP3 (*.mp3* files) in a web page. You must include path of the media file to play; all other parameters are optional. If you specify only a path, the player uses default settings set by the current version of MediaPlayer, such as:

- The video is displayed using its default width and height.
- The video plays automatically when the page loads.
- The video plays once (it doesn't loop).
- The player displays the full set of controls in the user interface.
- The video plays in a window.

The Silverlight Player

The `Silverlight` player of the `Video` helper lets you play Windows Media Video (*.wmv* files), Windows Media Audio (*.wma* files), and MP3 (*.mp3* files). You must set the path parameter to point to a Silverlight-based application package (*.xap* file). You also must set the width and height parameters. All other parameters are optional. When you use the Silverlight player for video, if you set only the required parameters, the Silverlight player displays the video without a background color.

> **NOTE**
>
> In case you don't already know Silverlight: the *.xap* file is a compressed file that contains layout instructions in a *.xaml* file, managed code in assemblies, and optional resources. You can create a *.xap* file in Visual Studio as a Silverlight application project.

The `Silverlight` video player uses both the settings that you provide for the player and the settings that are provided in the *.xap* file.

TIP

MIME Types

When a browser downloads a file, the browser makes sure that the file type matches the MIME type that's specified for the document that's being rendered. The MIME type is the content type or media type of a file. The `Video` helper uses the following MIME types:

- `application/x-shockwave-flash`
- `application/x-mplayer2`
- `application/x-silverlight-2`

Playing Flash (.swf) Videos

This procedure shows you how to play a Flash video named *sample.swf*. The procedure assumes that you've got a folder named *Media* on your site and that the *.swf* file is in that folder.

1. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already added it.

2. In the website, add a page and name it *FlashVideo.cshtml*.

3. Add the following markup to the page:

```
<!DOCTYPE html>
<html>
<head>
    <title>Flash Video</title>
</head>
<body>
    @Video.Flash(path: "Media/sample.swf",
                 width: "400",
                 height: "600",
                 play: true,
                 loop: true,
                 menu:  false,
                 bgColor: "red",
                 quality: "medium",
                 scale: "exactfit",
                 windowMode: "transparent")
</body>
</html>
```

4. Run the page in a browser. (Make sure the page is selected in the **Files** workspace before you run it.) The page is displayed and the video plays automatically.

You can set the `quality` parameter for a Flash video to `low`, `autolow`, `autohigh`, `medium`, `high`, and `best`:

```
<!-- Set the Flash video quality -->
@Video.Flash(path: "Media/sample.swf", quality: "autohigh")
```

You can change the Flash video to play at a specific size using the `scale` parameter, which you can set to the following:

- `showall`. This makes the entire video visible while maintaining the original aspect ratio. However, you might end up with borders on each side.
- `noorder`. This scales the video while maintaining the original aspect ratio, but it might be cropped.
- `exactfit`. This makes the entire video visible without preserving the original aspect ratio, but distortion may occur.

If you don't specify a `scale` parameter, the entire video will be visible and the original aspect ratio will be maintained without any cropping. The following example shows how to use the `scale` parameter:

```
<!-- Set the Flash video to an exact size -->
@Video.Flash(path: "Media/sample.swf", width: "1000", height: "100",
    scale: "exactfit")
```

The Flash player supports a video mode setting named `windowMode`. You can set this to `window`, `opaque`, and `transparent`. By default, the `windowMode` is set to `window`, which displays the video in a separate window on the web page. The `opaque` setting hides everything behind the video on the web page. The `transparent` setting lets the background of the web page show through the video, assuming any part of the video is transparent.

Playing MediaPlayer (*.wmv*) Videos

The following procedure shows you how to play a Window Media video named *sample.wmv* that's in the *Media* folder.

1. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already.

2. Create a new page named *MediaPlayerVideo.cshtml*.

3. Add the following markup to the page:

```
<!DOCTYPE html>
<html>
<head>
  <title>MediaPlayer Video</title>
</head>
<body>
    @Video.MediaPlayer(
        path: "Media/sample.wmv",
        width: "400",
        height: "600",
        autoStart: true,
        playCount: 2,
        uiMode:  "full",
        stretchToFit: true,
        enableContextMenu: true,
        mute: false,
        volume: 75)
</body>
</html>
```

4. Run the page in a browser. The video loads and plays automatically.

You can set `playCount` to an integer that indicates how many times to play the video automatically:

```
<!-- Set the MediaPlayer video playCount -->
@Video.MediaPlayer(path: "Media/sample.wmv", playCount: 2)
```

The `uiMode` parameter lets you specify which controls show up in the user interface. You can set `uiMode` to `invisible`, `none`, `mini`, or `full`. If you don't specify a `uiMode` parameter, the video will be displayed with the status window, seek bar, control buttons, and volume controls in addition to the video window. These controls will also be displayed if you use the player to play an audio file. Here's an example of how to use the `uiMode` parameter:

```
<!-- Set the MediaPlayer control UI -->
@Video.MediaPlayer(path: "Media/sample.wmv", uiMode: "mini")
```

By default, audio is on when the video plays. You can mute the audio by setting the `mute` parameter to true:

```
<!-- Play the MediaPlayer video without audio -->
@Video.MediaPlayer(path: "Media/sample.wmv", mute: true)
```

You can control the audio level of the MediaPlayer video by setting the `volume` parameter to a value between 0 and 100. The default value is 50. Here's an example:

```
<!-- Play the MediaPlayer video without audio -->
@Video.MediaPlayer(path: "Media/sample.wmv", volume: 75)
```

Playing Silverlight Videos

This procedure shows you how to play video contained in a Silverlight *.xap* page that's in a folder named *Media*.

1. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already .
2. Create a new page named *SilverlightVideo.cshtml*.
3. Add the following markup to the page:

```
<!DOCTYPE html>
<html>
<head>
  <title>Silverlight Video</title>
</head>
<body>
    @Video.Silverlight(
        path: "Media/sample.xap",
        width: "400",
        height: "600",
        bgColor: "red",
        autoUpgrade: true)
</body>
</html>
```

4. Run the page in a browser.

Creating and Using a Helper in an ASP.NET Web Pages (Razor) Site

2/20/2020 • 3 minutes to read • Edit Online

by Tom FitzMacken

This article describes how to create a helper in an ASP.NET Web Pages (Razor) website. A *helper* is a reusable component that includes code and markup to perform a task that might be tedious or complex.

What you'll learn:

- How to create and use a simple helper.

These are the ASP.NET features introduced in the article:

- The `@helper` syntax.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

Overview of Helpers

If you need to perform the same tasks on different pages in your site, you can use a helper. ASP.NET Web Pages includes a number of helpers, and there are many more that you can download and install. (A list of the built-in helpers in ASP.NET Web Pages is listed in the ASP.NET API Quick Reference.) If none of the existing helpers meet your needs, you can create your own helper.

A helper lets you use a common block of code across multiple pages. Suppose that in your page you often want to create a note item that's set apart from normal paragraphs. Perhaps the note is created as a `<div>` element that's styled as a box with a border. Rather than add this same markup to a page every time you want to display a note, you can package the markup as a helper. You can then insert the note with a single line of code anywhere you need it.

Using a helper like this makes the code in each of your pages simpler and easier to read. It also makes it easier to maintain your site, because if you need to change how the notes look, you can change the markup in one place.

Creating a Helper

This procedure shows you how to create the helper that creates the note, as just described. This is a simple example, but the custom helper can include any markup and ASP.NET code that you need.

1. In the root folder of the website, create a folder named *App_Code*. This is a reserved folder name in ASP.NET where you can put code for components like helpers.
2. In the *App_Code* folder create a new *.cshtml* file and name it *MyHelpers.cshtml*.
3. Replace the existing content with the following:

```
@helper MakeNote(string content) {
  <div class="note"
       style="border: 1px solid black; width: 90%; padding: 5px; margin-left: 15px;">
    <p>
      <strong>Note</strong>   @content
    </p>
  </div>
}
```

The code uses the `@helper` syntax to declare a new helper named `MakeNote`. This particular helper lets you pass a parameter named `content` that can contain a combination of text and markup. The helper inserts the string into the note body using the `@content` variable.

Notice that the file is named *MyHelpers.cshtml*, but the helper is named `MakeNote`. You can put multiple custom helpers into a single file.

4. Save and close the file.

Using the Helper in a Page

1. In the root folder, create a new blank file called *TestHelper.cshtml*.

2. Add the following code to the file:

```
<!DOCTYPE html>
  <head>
    <title>Test Helpers Page</title>
  </head>
  <body>
    <p>This is some opening paragraph text.</p>

    <!-- Insert the call to your note helper here. -->
    @MyHelpers.MakeNote("My test note content.")

    <p>This is some following text.</p>
  </body>
</html>
```

To call the helper you created, use `@` followed by the file name where the helper is, a dot, and then the helper name. (If you had multiple folders in the *App_Code* folder, you could use the syntax `@FolderName.FileName.HelperName` to call your helper within any nested folder level). The text that you add in quotation marks within the parentheses is the text that the helper will display as part of the note in the web page.

3. Save the page and run it in a browser. The helper generates the note item right where you called the helper: between the two paragraphs.

Installing a Helper in an ASP.NET Web Pages (Razor) Site

2/20/2020 • 2 minutes to read • Edit Online

by Tom FitzMacken

This article describes how to install a helper in an ASP.NET Web Pages (Razor) website. A *helper* is a reusable component that includes code and markup to perform a task that might be tedious or complex.

What you'll learn:

- How to install a helper in a website created using WebMatrix 3.

Software versions used in the tutorial

- WebMatrix 3

Overview of Helpers

Some tasks that people often want to do on web pages require a lot of code or require extra knowledge. Examples include displaying a chart for data; putting a Twitter "Follow" button on a page; sending email from your website; cropping or resizing images; using PayPal for your site. To make it easy to do these kinds of things, ASP.NET Web Pages lets you use *helpers*. Helpers are components that you install for a site and that let you perform typical tasks by using just a line or two of Razor code.

ASP.NET Web Pages has a few helpers built in. However, many helpers are available in packages (add-ins) that are provided using the NuGet package manager. NuGet lets you select a package to install and then it takes care of all the details of the installation.

Installing a Helper in WebMatrix 3

1. In WebMatrix 3, click the **NuGet** button.

2. This launches the NuGet package manager and displays available packages. In the search box, enter a keyword for the helper you want to install.

3. Select the package and then click **Install**. Click **Yes** when asked if you want to install the package and indicate that you accept the terms.

   If this is the first time you've installed a helper, NuGet creates folders in your website for the code that makes up the helper.

4. To uninstall a helper, click the **Gallery** button, click the **Installed** tab, and pick the package you want to uninstall.

Installing the Twitter helper

The latest version of the Twitter API is not compatible with the Twitter helper you install through NuGet. Instead, see the Twitter Helper with WebMatrix topic for information about how to set up the Twitter helper in your project.

Twitter Helper with WebMatrix

Twitter Helper with ASP.NET Web Pages

2/20/2020 • 7 minutes to read • Edit Online

by Tom FitzMacken

IMPORTANT

Twitter Helpers are obsolete. For Twitter's latest engagement tools for websites, see Twitter for Websites Overview.

This topic and application show how to add a Twitter Helper to your WebMatrix 3 project. It contains the Twitter Helper code and shows how to call the helper methods.

This code for the Twitter.cshtml file was developed by **Tian Pan** of Microsoft.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

Introduction

This topic demonstrates how to add a Twitter Helper to your application and use Razor syntax to call the helper methods. The Twitter Helper makes it easy to incorporate Twitter buttons and widgets in your application. To use a Twitter widget, such as a user's timeline or the search results for a hashtag, you must first create the widget on Twitter. After creating your widget, you will receive a widget id. You pass this widget id as a parameter when calling the helper methods that show widget.

This topic was written for version 1.1 of the Twitter API. By directly adding the Twitter Helper code to your project, you can update the helper code if the Twitter API changes.

For information about installing WebMatrix, see Introducing ASP.NET Web Pages 2 - Getting Started.

Add Twitter Helper to your project

To add the Twitter Helper, first, add a folder named **App_Code** to your project. Then, create a file named **Twitter.cshtml**.

Replace the default code in Twitter.cshtml with the following code.

```
@* This Twitter helper is compatible with version 1.1 of the Twitter API. *@

@using System.Globalization

@* For more about the twitter follow button, please visit
```

```
   https://dev.twitter.com/docs/follow-button *@
@helper FollowButton(
            string userName,
            bool showCount = false,
            bool showUserName = true,
            bool largeButton = false,
            bool optOutOfTailoring = false,
            string language = "",
            bool alignLeft = true)
{
    var showCountAttribute = new HtmlString(showCount ? "" : "data-show-count=\"false\"");
    var showUserNameAttribute = new HtmlString(showUserName ? "" : "data-show-screen-name=\"false\"");
    var largeButtonAttribute = new HtmlString(largeButton ? "data-size=\"large\"" : "");
    var optOutOfTailoringAttribute = new HtmlString(optOutOfTailoring ? "data-dnt=\"true\"" : "");
    var languageAttribute = new HtmlString(!language.IsEmpty() && !language.Equals("en",
StringComparison.OrdinalIgnoreCase) ? String.Format(CultureInfo.InvariantCulture, " data-lang=\"" +
HttpUtility.HtmlAttributeEncode(language) + "\"") : "");
    var alignAttribute = new HtmlString(alignLeft ? "" : "data-align=\"right\"");
    <a href="https://twitter.com/@HttpUtility.UrlEncode(userName)" class="twitter-follow-button"
@showCountAttribute @showUserNameAttribute @largeButtonAttribute @optOutOfTailoringAttribute
@languageAttribute @alignAttribute>Follow @@@userName)</a>
    <script>!function (d, s, id) { var js, fjs = d.getElementsByTagName(s)[0], p = /^http:/.test(d.location)
? 'http' : 'https'; if (!d.getElementById(id)) { js = d.createElement(s); js.id = id; js.src = p +
'://platform.twitter.com/widgets.js'; fjs.parentNode.insertBefore(js, fjs); } }(document, 'script', 'twitter-
wjs');</script>
}

@* For more about the tweet button, please visit https://dev.twitter.com/docs/tweet-button *@
@helper TweetButton(string url = "",
            string tweetText = "",
            bool showCount = true,
            string via = "",
            string recommend = "",
            string hashtag = "",
            bool largeButton = false,
            bool optOutOfTailoring = false,
            string language = "")
{
    var urlAttribute = new HtmlString(url.IsEmpty() ? "" : String.Format(CultureInfo.InvariantCulture, "
data-url=\"" + HttpUtility.HtmlAttributeEncode(url) + "\""));
    var tweetTextAttribute = new HtmlString(tweetText.IsEmpty() ? "" : "data-text=\"" +
HttpUtility.HtmlAttributeEncode(tweetText) + "\"");
    var showCountAttribute = new HtmlString(showCount ? "" : "data-show-count=\"false\"");
    var viaAttribute = new HtmlString(via.IsEmpty() ? "" : "data-via=\"" +
HttpUtility.HtmlAttributeEncode(via) + "\"");

HttpUtility.HtmlAttributeEncode(hashtag) + "\"");
    var largeButtonAttribute = new HtmlString(largeButton ? "data-size=\"large\"" : "");
    var optOutOfTailoringAttribute = new HtmlString(optOutOfTailoring ? "data-dnt=\"true\"" : "");
    var languageAttribute = new HtmlString(!language.IsEmpty() && !language.Equals("en",
StringComparison.OrdinalIgnoreCase) ? String.Format(CultureInfo.InvariantCulture, " data-lang=\"{0}\"",
HttpUtility.HtmlAttributeEncode(language)) : "");
    <a href="https://twitter.com/share" class="twitter-share-button" @urlAttribute @tweetTextAttribute
@showCountAttribute @viaAttribute @recommendAttribute @hashtagAttribute @largeButtonAttribute
@optOutOfTailoringAttribute @languageAttribute>Tweet</a>
    <script>!function (d, s, id) { var js, fjs = d.getElementsByTagName(s)[0], p = /^http:/.test(d.location)
? 'http' : 'https'; if (!d.getElementById(id)) { js = d.createElement(s); js.id = id; js.src = p +
'://platform.twitter.com/widgets.js'; fjs.parentNode.insertBefore(js, fjs); } }(document, 'script', 'twitter-
wjs');</script>
}

@helper TimeLine(string userName,
            string widgetId,
            string theme = "",
            string linkColor = "",
            string language = "",
            int? tweetLimit = null,
```

```
            string relatedUsers = "",
            string ariaPolite = "",
            int? width = null,
            int? height = null,
            string title = "Tweets")
{
    var themeAttribute = new HtmlString(theme.IsEmpty() ? "" : "data-theme=\"" + theme + "\"");
    var linkColorAttribute = new HtmlString(linkColor.IsEmpty() ? "" : "data-link-color=\"" + linkColor +
"\"");
    var languageAttribute = new HtmlString(!language.IsEmpty() && !language.Equals("en",
StringComparison.OrdinalIgnoreCase) ? String.Format(CultureInfo.InvariantCulture, " data-lang=\"{0}\"",
HttpUtility.HtmlAttributeEncode(language)) : "");
    var relatedUsersAttribute = new HtmlString(relatedUsers.IsEmpty() ? "" : "data-related=\"" + relatedUsers
+ "\"");
    var ariaPoliteAttribute = new HtmlString(ariaPolite.IsEmpty() ? "" : "data-aria-polite=\"" + ariaPolite +
"\"");
    <a class="twitter-timeline" href="https://twitter.com/@userName" width="@width.ToString()"
height="@height.ToString()" data-widget-id="@HttpUtility.HtmlEncode(widgetId)" @themeAttribute
@linkColorAttribute @languageAttribute data-tweet-limit="@tweetLimit.ToString()" @relatedUsersAttribute
@ariaPoliteAttribute>@title</a>
    <script>!function (d, s, id) { var js, fjs = d.getElementsByTagName(s)[0], p = /^http:/.test(d.location)
? 'http' : 'https'; if (!d.getElementById(id)) { js = d.createElement(s); js.id = id; js.src = p +
"://platform.twitter.com/widgets.js"; fjs.parentNode.insertBefore(js, fjs); } }(document, "script", "twitter-
wjs");</script>
}

@helper Profile(string userName,
            string widgetId,
            string theme = "",
            string linkColor = "",
            string language = "",
            int? tweetLimit = null,
            string relatedUsers = "",
            string ariaPolite = "",
            int? width = null,
            int? height = null)
{
    @Twitter.TimeLine(userName, widgetId, theme, linkColor, language, tweetLimit, relatedUsers, ariaPolite,
width, height, "Tweets by @" + HttpUtility.HtmlEncode(userName));
}

@helper Faves(string userName,
            string widgetId,
            string theme = "",
            string linkColor = "",
            string language = "",
            int? tweetLimit = null,
            string relatedUsers = "",
            string ariaPolite = "",
            int? width = null,
            int? height = null)
{
    @Twitter.TimeLine(userName + "/favorites", widgetId, theme, linkColor, language, tweetLimit,
relatedUsers, ariaPolite, width, height, "Favorite Tweets by @" + HttpUtility.HtmlEncode(userName));
}

@helper List(string userName,
            string list,
            string widgetId,
            string theme = "",
            string linkColor = "",
            string language = "",
            int? tweetLimit = null,
            string relatedUsers = "",
            string ariaPolite = "",
            int? width = null,
            int? height = null)
{
    @Twitter.TimeLine(userName + "/" + list, widgetId, theme, linkColor, language, tweetLimit, relatedUsers,
```

```
    @Twitter.TimeLine(userName + "/" + list, widgetId, theme, linkColor, language, tweetLimit, relatedUsers,
ariaPolite, width, height, "Tweets from @" + HttpUtility.HtmlEncode(userName) + "/" +
HttpUtility.HtmlEncode(list));
}

@helper Search(string query,
            string widgetId,
            string theme = "",
            string linkColor = "",
            string language = "",
            int? tweetLimit = null,
            string relatedUsers = "",
            string ariaPolite = "",
            int? width = null,
            int? height = null)
{
    @Twitter.TimeLine("search?q=" + HttpUtility.UrlEncode(query), widgetId, theme, linkColor, language,
tweetLimit, relatedUsers, ariaPolite, width, height, "Tweets about \"" + HttpUtility.HtmlEncode(query) +
"\"");
}
```

Call Twitter methods from your web pages

The following example shows how to use the Twitter Helper methods from a page in your project. In your project, you will want to replace the parameter values with values that are relevant to your needs. You can use the provided widget ids to explore how the methods work, but you will want to generate your own widgets for your project.

Not all of the parameters shown below are required. The optional parameters are used to customize how the button or widget is displayed. For example, the Follow Button only requires the user name to follow, but the example shows how to include the number of followers, and how specify the size of the button and the language.

```
<!DOCTYPE html>

<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title>Show the Twitter Helper</title>
    </head>
    <body>
        <h1>Twitter Buttons and Widgets</h1>

        <h2>1. Follow Button</h2>
        <p>@Twitter.FollowButton(userName: "aspnet", showCount: true, largeButton: false, language: "es")</p>

        <h2>2. Tweet Button</h2>
        <p>@Twitter.TweetButton(url: "http://www.asp.net/mvc", largeButton: true, hashtag: "awesome")</p>

        <h2>3. User Timeline (Profile)</h2>
        <p>@Twitter.Profile("aspnet", "370310677673422848")</p>

        <h2>4. Favorites</h2>
        <p>@Twitter.Faves("Microsoft", "372486349795753984")</p>

        <h2>5. List</h2>
        <p>@Twitter.List("MS_Consumer_Bands", "Microsoft", "372485258974748672")</p>

        <h2>6. Search</h2>
        <p>@Twitter.Search("#asp.net", "370310477957435392")</p>
    </body>
</html>
```

See the results

The above code produces the following buttons and widgets. These buttons and widgets are fully-functional, not screenshots. The Follow Button is displayed in Spanish because the language parameter was set to **es**.

Follow Button

Follow @aspnet)

```
<script>!function (d, s, id) { var js, fjs = d.getElementsByTagName(s)[0], p = /^http:/.test(d.location) ?
'http' : 'https'; if (!d.getElementById(id)) { js = d.createElement(s); js.id = id; js.src = p +
'://platform.twitter.com/widgets.js'; fjs.parentNode.insertBefore(js, fjs); } }(document, 'script', 'twitter-
wjs');</script>
```

Tweet Button

Tweet

```
<script>!function (d, s, id) { var js, fjs = d.getElementsByTagName(s)[0], p = /^http:/.test(d.location) ?
'http' : 'https'; if (!d.getElementById(id)) { js = d.createElement(s); js.id = id; js.src = p +
'://platform.twitter.com/widgets.js'; fjs.parentNode.insertBefore(js, fjs); } }(document, 'script', 'twitter-
wjs');</script>
```

User Timeline (Profile)

Tweets by @aspnet

```
<script>!function (d, s, id) { var js, fjs = d.getElementsByTagName(s)[0], p = /^http:/.test(d.location) ?
'http' : 'https'; if (!d.getElementById(id)) { js = d.createElement(s); js.id = id; js.src = p +
"://platform.twitter.com/widgets.js"; fjs.parentNode.insertBefore(js, fjs); } }(document, "script", "twitter-
wjs");</script>
```

Favorites

Favorite Tweets by Microsoft

```
<script>!function (d, s, id) { var js, fjs = d.getElementsByTagName(s)[0], p = /^http:/.test(d.location) ?
'http' : 'https'; if (!d.getElementById(id)) { js = d.createElement(s); js.id = id; js.src = p +
"://platform.twitter.com/widgets.js"; fjs.parentNode.insertBefore(js, fjs); } }(document, "script", "twitter-
wjs");</script>
```

List

Tweets from @Microsoft/MS_Consumer_Bands

```
<script>!function (d, s, id) { var js, fjs = d.getElementsByTagName(s)[0], p = /^http:/.test(d.location) ?
'http' : 'https'; if (!d.getElementById(id)) { js = d.createElement(s); js.id = id; js.src = p +
"://platform.twitter.com/widgets.js"; fjs.parentNode.insertBefore(js, fjs); } }(document, "script", "twitter-
wjs");</script>
```

Search

Tweets about "#asp.net"

```
<script>!function (d, s, id) { var js, fjs = d.getElementsByTagName(s)[0], p = /^http:/.test(d.location) ?
'http' : 'https'; if (!d.getElementById(id)) { js = d.createElement(s); js.id = id; js.src = p +
"://platform.twitter.com/widgets.js"; fjs.parentNode.insertBefore(js, fjs); } }(document, "script", "twitter-
wjs");</script>
```

Displaying Maps in an ASP.NET Web Pages (Razor) Site

2/20/2020 • 4 minutes to read • Edit Online

by Tom FitzMacken

This article explains how to display interactive maps on pages in an ASP.NET Web Pages (Razor) website based on mapping services provided by Bing, Google, MapQuest, and Yahoo.

What you'll learn:

- How to generate a map based on an address.
- How to generate a map based on latitude and longitude coordinates.
- How to register a Bing Maps Developer Account and get a key to use with Bing Maps.

This is the ASP.NET feature introduced in the article:

- The `Maps` helper.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- WebMatrix 2

This tutorial also works with WebMatrix 3.

In Web Pages, you can display maps on a page by using `Maps` helper. You can generate maps based either on an address or on a set of longitude and latitude coordinates. The `Maps` class lets you call into popular map engines including Bing, Google, MapQuest, and Yahoo.

The steps for adding mapping to a page are the same regardless of which of the map engines you call. You just add a JavaScript file reference that makes available methods to display the map, and then you call methods of the `Maps` helper.

You choose a map service based on which `Maps` helper method you use. You can use any of these:

- `Maps.GetBingHtml`
- `Maps.GetGoogleHtml`
- `Maps.GetYahooHtml`
- `Maps.GetMapQuestHtml`

Installing the Pieces You Need

To display maps, you need these pieces:

- The `Maps` helper. This helper is in version 2 of the ASP.NET Web Helpers Library. If you haven't already added the library, you can install it in your site as a NuGet package. For details, see Installing Helpers in an ASP.NET Web Pages Site. (In the Gallery, search for the `microsoft-web-helpers` package.)
- The jQuery library. Several of the WebMatrix site templates already include jQuery libraries in their *Script* folders. If you do not have these libraries, you can download the latest jQuery library directly from the

jQuery.org site. Or you can create a new site using a template (for example, the **Starter Site** template) and then copy the jQuery files from that site to your current site.

Finally, if you want to use Bing maps, you must first create a (free) account and get a key. To get a key, follow these steps:

1. Create an account on the Bing Maps Developer Account. You must have a Microsoft account (Windows Live ID) as well.

   You can specify that you want to use the key for **Evaluation/Test**. If you are testing the mapping function on your own computer using WebMatrix and IIS Express, go the **Site** workspace and note the URL of your site (for example, `http://localhost:50408`, although your port number will probably be different). You can use this *localhost* address as the site when you register.

2. After you have registered for an account, go to the Bing Maps Account Center and click **Create or view keys**:

3. Record the key that Bing creates.

Creating a Map Based on an Address (Using Google)

The following example shows how to create a page that renders a map based on an address. This example shows how to use Google Maps.

1. Create a file named *MapAddress.cshtml* in the root of the site. This page will generate a map based on an address that you pass to it.

2. Copy the following code into the file, overwriting the existing content.

```
<!DOCTYPE html>
<html lang="en">
<head>
  <title>Map an Address</title>
  <script src="~/Scripts/jquery-1.6.4.min.js" type="text/javascript"></script>
</head>

<body>
    <h1>Map an Address</h1>
    <form method="post">
        <fieldset>
          <div>
            <label for="address">Address:</label>
            <input style="width: 300px" type="text" name="address" value="@Request["address"]"/>
            <input type="submit" value="Map It!" />
           </div>
        </fieldset>
    </form>
    @if(IsPost) {
        @Maps.GetGoogleHtml(Request.Form["address"],
            width: "400",
            height: "400")
    }
</body>
</html>
```

Notice the following features of the page:

- The `<script>` element in the `<head>` element. In the example, the `<script>` element references the *jquery-1.6.4.min.js* file, which is a minified (compressed) version of the jQuery library, version 1.6.4. Note that the reference assumes that the *.js* file is in the *Scripts* folder of your site.

  > **NOTE**
  > If you're using a different version of the jQuery library, just make sure that you're pointing to that version correctly.

- The call to the `@Maps.GetGoogleHtml` in the body of the page. To map an address, you must pass an address string. The methods for the other map engines work in a similar way (`@Maps.GetYahooHtml`, `@Maps.GetMapQuestHtml`).

3. Run the page and enter an address. The page displays a map, based on Google Maps, that shows the location that you specified.

Creating a Map Based on Latitude and Longitude Coordinates (Using Bing)

This example shows how to create a map based on coordinates. This example shows how to use Bing maps and how to include your Bing key. (You can create a map based on coordinates using the other map engines also, without using a Bing key.)

1. Create a file named *MapCoordinates.cshtml* in the root of the site and replace the existing content with the following code and markup:

```
<!DOCTYPE html>
<html lang="en"><head>
  <title>Map Coordinates</title>
  <script src="~/Scripts/jquery-1.6.4.min.js" type="text/javascript"></script>
</head>
<body>
  <h1>Map Coordinates</h1>
  <form method="post">
    <fieldset>
    <div>
      <label for="latitude">Latitude:   </label>
        <input type="text" name="latitude" value="@Request["latitude"]"/>
    </div>
    <div>
      <label for="longitude">Longitude:</label>
      <input type="text" name="longitude" value="@Request["longitude"]"/>
    </div>
    <div>
      <input type="submit" value="Map It!" />
    </div>
    </fieldset>
  </form>
  @if(IsPost) {
      @Maps.GetBingHtml(key: "your-key-here",
          latitude: Request["latitude"],
          longitude: Request["longitude"],
          width: "300",
          height: "300"
       )
    }
</body>
</html>
```

2. Replace `your-key-here` with the Bing Maps key that you generated earlier.

3. Run the *MapCoordinates.cshtml* page, enter latitude and longitude coordinates, and then click the **Map It!** button. (If you don't know any coordinates, try the following. This is a location on the Microsoft Redmond campus.)

   - Latitude: 47.6781005859375
   - Longitude: -122.158317565918

   The page is displayed using the coordinates that you specified.

- Rendering ASP.NET Web Pages Sites for Mobile Devices

Rendering ASP.NET Web Pages (Razor) Sites for Mobile Devices

2/20/2020 • 3 minutes to read • Edit Online

by Tom FitzMacken

This article describes how to create pages in an ASP.NET Web Pages (Razor) site that will render appropriately on mobile devices.

What you'll learn:

- How to use a naming convention to specify that a page is designed specifically for mobile devices.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

ASP.NET Web Pages lets you create custom displays for rendering content on mobile or other devices.

The simplest way to create device-specific page in an ASP.NET Web Pages site is by using a file-naming pattern like this: *FileName.Mobile.cshtml*. You can create two versions of a page (for example, one named *MyFile.cshtml* and one named *MyFile.Mobile.cshtml*). At run time, when a mobile device requests *MyFile.cshtml*, ASP.NET renders the content from *MyFile.Mobile.cshtml*. Otherwise, *MyFile.cshtml* is rendered.

The following example shows how to enable mobile rendering by adding a content page for mobile devices. *Page1.cshtml* contains content plus a navigation sidebar. *Page1.Mobile.cshtml* contains the same content, but omits the sidebar.

1. In an ASP.NET Web Pages site, create a file named *Page1.cshtml* and replace the current content with following markup.

```
<!DOCTYPE html>

<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title></title>
        <style type="text/css">
            #navigation {
                position: absolute;
                top: 0;
                left: 0;
                width: 10em;
            }
            #content {
            margin-left: 13em;
                margin-right: 10em;
            }
        </style>
    </head>
    <body>
        <div id="navigation">
            <h3>Related Sites</h3>
            <ul>
                <li><a href="http://www.adventure-works.com/">Adventure Works</a></li>
                <li><a href="http://www.contoso.com/">Contoso, Ltd</a></li>
                <li><a href="http://www.treyresearch.net/">Trey Research</a></li>
            </ul>
        </div>
        <div id="content">
            <h1>Lorem ipsum dolor</h1>
            <p>Lorem ipsum dolor sit amet, consetetur sadipscing elitr, sed diam nonumy
            eirmod tempor invidunt ut labore et dolore magna aliquyam erat, sed diam voluptua.
            At vero eos et accusam et justo duo dolores et ea rebum. Stet clita kasd gubergren,
            no sea takimata sanctus est Lorem ipsum dolor sit amet. Lorem ipsum dolor sit
            amet, consetetur sadipscing elitr, sed diam nonumy eirmod tempor invidunt ut
            labore et dolore magna aliquyam erat, sed diam voluptua. </p>
            <p>At vero eos et accusam et justo duo dolores et ea rebum. Stet clita kasd
            gubergren, no sea takimata sanctus est Lorem ipsum dolor sit amet. Lorem ipsum
            dolor sit amet, consetetur sadipscing elitr, sed diam nonumy eirmod tempor invidunt
            ut labore et dolore magna aliquyam erat, sed diam voluptua. At vero eos et accusam
            et justo duo dolores et ea rebum. Stet clita kasd gubergren, no sea takimata
            sanctus est Lorem ipsum dolor sit amet.</p>
        </div>
    </body>
</html>
```

2. Create a file named *Page1.Mobile.cshtml* and replace the existing content with the following markup. Notice that the mobile version of the page omits the navigation section for better rendering on a smaller screen.

```
<!DOCTYPE html>

<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title></title>
        <style type="text/css">
            #content {
            margin-left: 2em;
                margin-right: 5em;
            }
        </style>
    </head>
    <body>
        <div id="content">
            <h1>Lorem ipsum dolor</h1>
            <p>Lorem ipsum dolor sit amet, consetetur sadipscing elitr, sed diam nonumy
            eirmod tempor invidunt ut labore et dolore magna aliquyam erat, sed diam voluptua.
            At vero eos et accusam et justo duo dolores et ea rebum. Stet clita kasd gubergren,
            no sea takimata sanctus est Lorem ipsum dolor sit amet. Lorem ipsum dolor sit
            amet, consetetur sadipscing elitr, sed diam nonumy eirmod tempor invidunt ut
            labore et dolore magna aliquyam erat, sed diam voluptua. </p>
            <p>At vero eos et accusam et justo duo dolores et ea rebum. Stet clita kasd
            gubergren, no sea takimata sanctus est Lorem ipsum dolor sit amet. Lorem ipsum
            dolor sit amet, consetetur sadipscing elitr, sed diam nonumy eirmod tempor invidunt
            ut labore et dolore magna aliquyam erat, sed diam voluptua. At vero eos et accusam
            et justo duo dolores et ea rebum. Stet clita kasd gubergren, no sea takimata
            sanctus est Lorem ipsum dolor sit amet.</p>
        </div>
    </body>
</html>
```

3. Run a desktop browser and browse to *Page1.cshtml*.

4. Run a mobile browser (or a mobile device emulator) and browse to *Page1.cshtml*. (Notice that you do not include *.mobile.* as part of the URL.) Even though the request is to *Page1.cshtml*, ASP.NET renders *Page1.Mobile.cshtml*.

Lorem ipsum dolor

Lorem ipsum dolor sit amet, consetetur sadipscing elitr, sed diam nonumy eirmod tempor invidunt ut labore et dolore magna aliquyam erat, sed diam voluptua. At vero eos et accusam et justo duo dolores et ea rebum. Stet clita kasd gubergren, no sea takimata sanctus est Lorem ipsum dolor sit amet. Lorem ipsum dolor sit amet, consetetur sadipscing elitr, sed diam nonumy eirmod tempor invidunt ut labore et dolore magna aliquyam erat, sed diam voluptua.

NOTE

To test mobile pages, you can use a mobile device simulator that runs on a desktop computer. This tool lets you test web pages as they would look on mobile devices (that is, typically with a much smaller display area). One example of a simulator is the User Agent Switcher add-on for Mozilla Firefox, which lets you emulate various mobile browsers from a desktop version of Firefox.

Introduction to Working with a Database in ASP.NET Web Pages (Razor) Sites

2/20/2020 • 25 minutes to read • Edit Online

by Tom FitzMacken

This article describes how to use Microsoft WebMatrix tools to create a database in an ASP.NET Web Pages (Razor) website, and how to create pages that let you display, add, edit, and delete data.

What you'll learn:

- How to create a database.
- How to connect to a database.
- How to display data in a web page.
- How to insert, update, and delete database records.

These are the features introduced in the article:

- Working with a Microsoft SQL Server Compact Edition database.
- Working with SQL queries.
- The `Database` class.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- WebMatrix 2

This tutorial also works with WebMatrix 3. You can use ASP.NET Web Pages 3 and Visual Studio 2013 (or Visual Studio Express 2013 for Web); however, the user interface will be different.

Introduction to Databases

Imagine a typical address book. For each entry in the address book (that is, for each person) you have several pieces of information such as first name, last name, address, email address, and phone number.

A typical way to picture data like this is as a table with rows and columns. In database terms, each row is often referred to as a record. Each column (sometimes referred to as fields) contains a value for each type of data: first name, last name, and so on.

ID	FIRSTNAME	LASTNAME	ADDRESS	EMAIL	PHONE
1	Jim	Abrus	210 100th St SE Orcas WA 98031	jim@contoso.com	555 0100
2	Terry	Adams	1234 Main St. Seattle WA 99011	terry@cohowinery.com	555 0101

For most database tables, the table has to have a column that contains a unique identifier, like a customer number, account number, etc. This is known as the table's *primary key*, and you use it to identify each row in the table. In the example, the ID column is the primary key for the address book.

With this basic understanding of databases, you're ready to learn how to create a simple database and perform operations such as adding, modifying, and deleting data.

> **TIP**
>
> **Relational Databases**
>
> You can store data in lots of ways, including text files and spreadsheets. For most business uses, though, data is stored in a relational database.
>
> This article doesn't go very deeply into databases. However, you might find it useful to understand a little about them. In a relational database, information is logically divided into separate tables. For example, a database for a school might contain separate tables for students and for class offerings. The database software (such as SQL Server) supports powerful commands that let you dynamically establish relationships between the tables. For example, you can use the relational database to establish a logical relationship between students and classes in order to create a schedule. Storing data in separate tables reduces the complexity of the table structure and reduces the need to keep redundant data in tables.

Creating a Database

This procedure shows you how to create a database named SmallBakery by using the SQL Server Compact Database design tool that's included in WebMatrix. Although you can create a database using code, it's more typical to create the database and database tables using a design tool like WebMatrix.

1. Start WebMatrix, and on the Quick Start page, click **Site From Template**.
2. Select **Empty Site**, and in the **Site Name** box enter "SmallBakery" and then click **OK**. The site is created and displayed in WebMatrix.
3. In the left pane, click the **Databases** workspace.
4. In the ribbon, click **New Database**. An empty database is created with the same name as your site.
5. In the left pane, expand the **SmallBakery.sdf** node and then click **Tables**.
6. In the ribbon, click **New Table**. WebMatrix opens the table designer.

7. Click in the **Name** column and enter "Id".
8. In the **Data Type** column, select **int**.
9. Set the **Is Primary Key?** and **Is Identify?** options to **Yes**.

As the name suggests, **Is Primary Key** tells the database that this will be the table's primary key. **Is Identity** tells the database to automatically create an ID number for every new record and to assign it the next sequential number (starting at 1).

10. Click in the next row. The editor starts a new column definition.
11. For the Name value, enter "Name".
12. For **Data Type**, choose "nvarchar" and set the length to 50. The *var* part of `nvarchar` tells the database that the data for this column will be a string whose size might vary from record to record. (The *n* prefix represents *national*, indicating that the field can hold character data that represents any alphabet or writing system — that is, that the field holds Unicode data.)
13. Set the **Allow Nulls** option to **No**. This will enforce that the *Name* column is not left blank.
14. Using this same process, create a column named *Description*. Set **Data Type** to "nvarchar" and 50 for the length, and set **Allow Nulls** to false.
15. Create a column named *Price*. Set **Data Type to "money"** and set **Allow Nulls** to false.
16. In the box at the top, name the table "Product".

    When you're done, the definition will look like this:

17. Press Ctrl+S to save the table.

Adding Data to the Database

Now you can add some sample data to your database that you'll work with later in the article.

1. In the left pane, expand the **SmallBakery.sdf** node and then click **Tables**.
2. Right-click the Product table and then click **Data**.
3. In the edit pane, enter the following records:

NAME	DESCRIPTION	PRICE
Bread	Baked fresh every day.	2.99
Strawberry Shortcake	Made with organic strawberries from our garden.	9.99
Apple Pie	Second only to your mom's pie.	12.99
Pecan Pie	If you like pecans, this is for you.	10.99

NAME	DESCRIPTION	PRICE
Lemon Pie	Made with the best lemons in the world.	11.99
Cupcakes	Your kids and the kid in you will love these.	7.99

Remember that you don't have to enter anything for the *Id* column. When you created the *Id* column, you set its **Is Identity** property to true, which causes it to automatically be filled in.

When you're finished entering the data, the table designer will look like this:

Table - (SmallBakery.sdf).Product

Id	Name	Description	Price
1	Bread	Baked fresh every day	2.99
2	Strawberry Shortcake	Made with organic strawberries from our garden	9.99
3	Apple Pie	Second only to your mom's pie	12.99
4	Pecan Pie	If you like pecans, this is for you.	10.99
5	Lemon Pie	Made with the best lemons in the world.	11.99
6	Cupcakes	Your kids and the kid in you will love these.	7.99

4. Close the tab that contains the database data.

Displaying Data from a Database

Once you've got a database with data in it, you can display the data in an ASP.NET web page. To select the table rows to display, you use a SQL statement, which is a command that you pass to the database.

1. In the left pane, click the **Files** workspace.
2. In the root of the website, create a new CSHTML page named *ListProducts.cshtml*.
3. Replace the existing markup with the following:

```
@{
    var db = Database.Open("SmallBakery");
    var selectQueryString = "SELECT * FROM Product ORDER BY Name";
 }
<!DOCTYPE html>
<html>
 <head>
   <title>Small Bakery Products</title>
   <style>
       table, th, td {
         border: solid 1px #bbbbbb;
         border-collapse: collapse;
         padding: 2px;
       }
    </style>
 </head>
 <body>
   <h1>Small Bakery Products</h1>
   <table>
       <thead>
           <tr>
               <th>Id</th>
               <th>Product</th>
               <th>Description</th>
       <th>Price</th>
           </tr>
       </thead>
       <tbody>
           @foreach(var row in db.Query(selectQueryString)){
            <tr>
               <td>@row.Id</td>
                   <td>@row.Name</td>
                   <td>@row.Description</td>
                   <td>@row.Price</td>
            </tr>
           }
       </tbody>
   </table>
 </body>
</html>
```

In the first code block, you open the *SmallBakery.sdf* file (database) that you created earlier. The `Database.Open` method assumes that the *.sdf* file is in your website's *App_Data* folder. (Notice that you don't need to specify the *.sdf* extension — in fact, if you do, the `Open` method won't work.)

> **NOTE**
>
> The *App_Data* folder is a special folder in ASP.NET that's used to store data files. For more information, see Connecting to a Database later in this article.

You then make a request to query the database using the following SQL `Select` statement:

```
SELECT * FROM Product ORDER BY Name
```

In the statement, `Product` identifies the table to query. The `*` character specifies that the query should return all the columns from the table. (You could also list columns individually, separated by commas, if you wanted to see only some of the columns.) The `Order By` clause indicates how the data should be sorted — in this case, by the *Name* column. This means that the data is sorted alphabetically based on the value of the *Name* column for each row.

In the body of the page, the markup creates an HTML table that will be used to display the data. Inside the `<tbody>` element, you use a `foreach` loop to individually get each data row that's returned by the query. For each data row, you create an HTML table row (`<tr>` element). Then you create HTML table cells (`<td>` elements) for each column. Each time you go through the loop, the next available row from the database is in the `row` variable (you set this up in the `foreach` statement). To get an individual column from the row, you can use `row.Name` or `row.Description` or whatever the name is of the column you want.

4. Run the page in a browser. (Make sure the page is selected in the **Files** workspace before you run it.) The page displays a list like the following:

Id	Product	Description	Price
3	Apple Pie	Second only to your mom's pie.	12.99
1	Bread	Baked fresh every day	2.99
6	Cupcakes	Your kids and the kid in you will love these.	7.99
5	Lemon Pie	Made with the best lemons in the world.	11.99
4	Pecan Pie	If you like pecans, this is for you.	10.99
2	Strawberry Shortcake	Made with organic strawberries from our garden.	9.99

TIP

Structured Query Language (SQL)

SQL is a language that's used in most relational databases for managing data in a database. It includes commands that let you retrieve data and update it, and that let you create, modify, and manage database tables. SQL is different than a programming language (like the one you're using in WebMatrix) because with SQL, the idea is that you tell the database what you want, and it's the database's job to figure out how to get the data or perform the task. Here are examples of some SQL commands and what they do:

```
SELECT Id, Name, Price FROM Product WHERE Price > 10.00 ORDER BY Name
```

This fetches the *Id*, *Name*, and *Price* columns from records in the *Product* table if the value of *Price* is more than 10, and returns the results in alphabetical order based on the values of the *Name* column. This command will return a result set that contains the records that meet the criteria, or an empty set if no records match.

```
INSERT INTO Product (Name, Description, Price) VALUES ("Croissant", "A flaky delight", 1.99)
```

This inserts a new record into the *Product* table, setting the *Name* column to "Croissant", the *Description* column to "A flaky delight", and the price to 1.99.

```
DELETE FROM Product WHERE ExpirationDate < "01/01/2008"
```

This command deletes records in the *Product* table whose expiration date column is earlier than January 1, 2008. (This assumes that the *Product* table has such a column, of course.) The date is entered here in MM/DD/YYYY format, but it should be entered in the format that's used for your locale.

The `Insert Into` and `Delete` commands don't return result sets. Instead, they return a number that tells you how many records were affected by the command.

For some of these operations (like inserting and deleting records), the process that's requesting the operation has to have appropriate permissions in the database. This is why for production databases you often have to supply a username and password when you connect to the database.

There are dozens of SQL commands, but they all follow a pattern like this. You can use SQL commands to create database tables, count the number of records in a table, calculate prices, and perform many more operations.

Inserting Data in a Database

This section shows how to create a page that lets users add a new product to the *Product* database table. After a new product record is inserted, the page displays the updated table using the *ListProducts.cshtml* page that you

created in the previous section.

The page includes validation to make sure that the data that the user enters is valid for the database. For example, code in the page makes sure that a value has been entered for all required columns.

1. In the website, create a new CSHTML file named *InsertProducts.cshtml*.

2. Replace the existing markup with the following:

```
@{
    Validation.RequireField("Name", "Product name is required.");
    Validation.RequireField("Description", "Product description is required.");
    Validation.RequireField("Price", "Product price is required.");

    var db = Database.Open("SmallBakery");
    var Name = Request.Form["Name"];
    var Description = Request.Form["Description"];
    var Price = Request.Form["Price"];

    if (IsPost && Validation.IsValid()) {
        // Define the insert query. The values to assign to the
        // columns in the Product table are defined as parameters
        // with the VALUES keyword.
        if(ModelState.IsValid) {
            var insertQuery = "INSERT INTO Product (Name, Description, Price) " +
                "VALUES (@0, @1, @2)";
            db.Execute(insertQuery, Name, Description, Price);
            // Display the page that lists products.
            Response.Redirect("~/ListProducts");
        }
    }
}

<!DOCTYPE html>
<html>
<head>
 <title>Add Products</title>
 <style type="text/css">
    label {float:left; width: 8em; text-align: right;
           margin-right: 0.5em;}
    fieldset {padding: 1em; border: 1px solid; width: 50em;}
    legend {padding: 2px 4px; border: 1px solid; font-weight:bold;}
    .validation-summary-errors {font-weight:bold; color:red;
           font-size: 11pt;}
 </style>
</head>
<body>
 <h1>Add New Product</h1>

 @Html.ValidationSummary("Errors with your submission:")

 <form method="post" action="">
   <fieldset>
     <legend>Add Product</legend>
     <div>
       <label>Name:</label>
       <input name="Name" type="text" size="50" value="@Name" />
     </div>
     <div>
       <label>Description:</label>
       <input name="Description" type="text" size="50"
           value="@Description" />
     </div>
     <div>
       <label>Price:</label>
       <input name="Price" type="text" size="50" value="@Price" />
     </div>
     <div>
       <label> </label>
       <input type="submit" value="Insert" class="submit" />
     </div>
   </fieldset>
 </form>
</body>
</html>
```

The body of the page contains an HTML form with three text boxes that let users enter a name, description, and price. When users click the **Insert** button, the code at the top of the page opens a connection to the *SmallBakery.sdf* database. You then get the values that the user has submitted by using the `Request` object and assign those values to local variables.

To validate that the user entered a value for each required column, you register each `<input>` element that you want to validate:

```
Validation.RequireField("Name", "Product name is required.");
Validation.RequireField("Description", "Product description is required.");
Validation.RequireField("Price", "Product price is required.");
```

The `Validation` helper checks that there is a value in each of the fields that you've registered. You can test whether all the fields passed validation by checking `Validation.IsValid()`, which you typically do before you process the information you get from the user:

```
if (IsPost && Validation.IsValid()) {
    // Process information here
}
```

(The `&&` operator means AND — this test is *If this is a form submission AND all the fields have passed validation*.)

If all the columns validated (none were empty), you go ahead and create a SQL statement to insert the data and then execute it as shown next:

```
var insertQuery =
    "INSERT INTO Product (Name, Description, Price) VALUES (@0, @1, @2)";
```

For the values to insert, you include parameter placeholders (`@0`, `@1`, `@2`).

> **NOTE**
> As a security precaution, always pass values to a SQL statement using parameters, as you see in the preceding example. This gives you a chance to validate the user's data, plus it helps protect against attempts to send malicious commands to your database (sometimes referred to as SQL injection attacks).

To execute the query, you use this statement, passing to it the variables that contain the values to substitute for the placeholders:

```
db.Execute(insertQuery, Name, Description, Price);
```

After the `Insert Into` statement has executed, you send the user to the page that lists the products using this line:

```
Response.Redirect("~/ListProducts");
```

If validation didn't succeed, you skip the insert. Instead, you have a helper in the page that can display the accumulated error messages (if any):

```
@Html.ValidationSummary("Errors with your submission:")
```

Notice that the style block in the markup includes a CSS class definition named `.validation-summary-errors`. This is the name of the CSS class that's used by default for the `<div>` element that contains any validation errors. In this case, the CSS class specifies that validation summary errors are displayed in red and in bold, but you can define the `.validation-summary-errors` class to display any formatting you like.

Testing the Insert Page

1. View the page in a browser. The page displays a form that's similar to the one that's shown in the following illustration.

2. Enter values for all the columns, but make sure that you leave the *Price* column blank.

3. Click **Insert**. The page displays an error message, as shown in the following illustration. (No new record is created.)

4. Fill the form out completely, and then click **Insert**. This time, the *ListProducts.cshtml* page is displayed and shows the new record.

Updating Data in a Database

After data has been entered into a table, you might need to update it. This procedure shows you how to create two pages that are similar to the ones you created for data insertion earlier. The first page displays products and lets users select one to change. The second page lets the users actually make the edits and save them.

> **NOTE**
>
> **Important** In a production website, you typically restrict who's allowed to make changes to the data. For information about how to set up membership and about ways to authorize users to perform tasks on the site, see Adding Security and Membership to an ASP.NET Web Pages Site.

1. In the website, create a new CSHTML file named *EditProducts.cshtml*.

2. Replace the existing markup in the file with the following:

```
@{
    var db = Database.Open("SmallBakery");
    var selectQueryString = "SELECT * FROM Product ORDER BY Name";

}
<!DOCTYPE html>
<html>
<head>
    <title>Edit Products</title>
    <style type="text/css">
        table, th, td {
          border: solid 1px #bbbbbb;
          border-collapse: collapse;
          padding: 2px;
        }
    </style>
</head>
<body>
    <h1>Edit Small Bakery Products</h1>
    <table>
      <thead>
        <tr>
          <th> </th>
          <th>Name</th>
          <th>Description</th>
          <th>Price</th>
        </tr>
      </thead>
      <tbody>
        @foreach (var row in db.Query(selectQueryString)) {
          <tr>
            <td><a href="@Href("~/UpdateProducts", row.Id)">Edit</a></td>
            <td>@row.Name</td>
            <td>@row.Description</td>
            <td>@row.Price</td>
          </tr>
        }
      </tbody>
    </table>
</body>
</html>
```

The only difference between this page and the *ListProducts.cshtml* page from earlier is that the HTML table in this page includes an extra column that displays an **Edit** link. When you click this link, it takes you to the *UpdateProducts.cshtml* page (which you'll create next) where you can edit the selected record.

Look at the code that creates the **Edit** link:

```
<a href="@Href("~/UpdateProducts", row.Id)">Edit</a></td>
```

This creates an HTML `<a>` element whose `href` attribute is set dynamically. The `href` attribute specifies the page to display when the user clicks the link. It also passes the `Id` value of the current row to the link. When the page runs, the page source might contain links like these:

```
<a href="UpdateProducts/1">Edit</a></td>
<a href="UpdateProducts/2">Edit</a></td>
<a href="UpdateProducts/3">Edit</a></td>
```

Notice that the `href` attribute is set to `UpdateProducts/n`, where *n* is a product number. When a user clicks one of these links, the resulting URL will look something like this:

```
http://localhost:18816/UpdateProducts/6
```

In other words, the product number to be edited will be passed in the URL.

3. View the page in a browser. The page displays the data in a format like this:

	Name	Description	Price
Edit	Apple Pie	Second only to your mom's pie.	12.99
Edit	Bread	Baked fresh every day.	2.99
Edit	Cherry Pie	Made with organic cherries from our garden.	8.99
Edit	Cupcakes	Your kids and the kid in you will love these.	7.99
Edit	Lemon Pie	Made with the best lemmons in the world.	11.99
Edit	Pecan Pie	If you like pecans this is fro you.	10.99
Edit	Strawberry Shortcake	Made with organic strawberries from our garden.	9.99

Next, you'll create the page that lets users actually update the data. The update page includes validation to validate the data that the user enters. For example, code in the page makes sure that a value has been entered for all required columns.

4. In the website, create a new CSHTML file named *UpdateProducts.cshtml*.

5. Replace the existing markup in the file with the following.

```
@{
    Validation.RequireField("Name", "Product name is required.");
    Validation.RequireField("Description", "Product description is required.");
    Validation.RequireField("Price", "Product price is required.");

    var Name = "";
    var Description = "";
    var Price = Decimal.Zero;

    var ProductId  = UrlData[0];
    if (ProductId.IsEmpty()) {
         Response.Redirect("~/EditProducts");
    }

    var db = Database.Open("SmallBakery");

    if (IsPost && Validation.IsValid()) {
        var updateQueryString =
            "UPDATE Product SET Name=@0, Description=@1, Price=@2 WHERE Id=@3" ;
        Name = Request["Name"];
        Description = Request["Description"];
        Price = Request["Price"].AsDecimal();
        db.Execute(updateQueryString, Name, Description, Price, ProductId);
        Response.Redirect(@Href("~/EditProducts"));
    }
    else {
        var selectQueryString = "SELECT * FROM Product WHERE Id=@0";

        var row = db.QuerySingle(selectQueryString, ProductId);
        Name = row.Name;
        Description = row.Description;
        Price = row.Price;
    }

}

<!DOCTYPE html>
<html>
<head>
  <title>Add Products</title>
  <style type="text/css">
     label { float: left; width: 8em; text-align: right;
             margin-right: 0.5em;}
```

```
            margin-right: 0.5em;}
      fieldset { padding: 1em; border: 1px solid; width: 35em;}
      legend { padding: 2px 4px;  border: 1px solid; font-weight: bold;}
      .validation-summary-errors {font-weight:bold; color:red; font-size:11pt;}
    </style>
  </head>
  <body>
    <h1>Update Product</h1>
     @Html.ValidationSummary("Errors with your submission:")
     <form method="post" action="">
       <fieldset>
         <legend>Update Product</legend>
         <div>
           <label>Name:</label>
           <input name="Name" type="text" size="50" value="@Name" />
         </div>
         <div>
           <label>Description:</label>
           <input name="Description" type="text" size="50"
              value="@Description" />
         </div>
         <div>
            <label>Price:</label>
            <input name="Price" type="text" size="50" value="@Price" />
         </div>
         <div>
            <label> </label>
            <input type="submit" value="Update" class="submit" />
         </div>
      </fieldset>
    </form>
  </body>
  </html>
```

The body of the page contains an HTML form where a product is displayed and where users can edit it. To get the product to display, you use this SQL statement:

```
SELECT * FROM Product WHERE Id=@0
```

This will select the product whose ID matches the value that's passed in the `@0` parameter. (Because *Id* is the primary key and therefore must be unique, only one product record can ever be selected this way.) To get the ID value to pass to this `Select` statement, you can read the value that's passed to the page as part of the URL, using the following syntax:

```
var ProductId  = UrlData[0];
```

To actually fetch the product record, you use the `QuerySingle` method, which will return just one record:

```
var row = db.QuerySingle(selectQueryString, ProductId);
```

The single row is returned into the `row` variable. You can get data out of each column and assign it to local variables like this:

```
var Name = row.Name;
var Description = row.Description;
var Price = row.Price;
```

In the markup for the form, these values are displayed automatically in individual text boxes by using embedded code like the following:

```
<input name="Name" type="text" size="50" value="@Name" />
```

That part of the code displays the product record to be updated. Once the record has been displayed, the user can edit individual columns.

When the user submits the form by clicking the **Update** button, the code in the `if(IsPost)` block runs. This gets the user's values from the `Request` object, stores the values in variables, and validates that each column has been filled in. If validation passes, the code creates the following SQL Update statement:

```
UPDATE Product SET Name=@0, Description=@1, Price=@2, WHERE ID=@3
```

In a SQL `Update` statement, you specify each column to update and the value to set it to. In this code, the values are specified using the parameter placeholders `@0`, `@1`, `@2`, and so on. (As noted earlier, for security, you should always pass values to a SQL statement by using parameters.)

When you call the `db.Execute` method, you pass the variables that contain the values in the order that corresponds to the parameters in the SQL statement:

```
db.Execute(updateQueryString, Name, Description, Price, ProductId);
```

After the `Update` statement has been executed, you call the following method in order to redirect the user back to the edit page:

```
Response.Redirect(@Href("~/EditProducts"));
```

The effect is that the user sees an updated listing of the data in the database and can edit another product.

6. Save the page.

7. Run the *EditProducts.cshtml* page (not the update page) and then click **Edit** to select a product to edit. The *UpdateProducts.cshtml* page is displayed, showing the record you selected.

8. Make a change and click **Update**. The products list is shown again with your updated data.

Deleting Data in a Database

This section shows how to let users delete a product from the *Product* database table. The example consists of two pages. In the first page, users select a record to delete. The record to be deleted is then displayed in a second page that lets them confirm that they want to delete the record.

> **NOTE**
>
> **Important** In a production website, you typically restrict who's allowed to make changes to the data. For information about how to set up membership and about ways to authorize user to perform tasks on the site, see Adding Security and Membership to an ASP.NET Web Pages Site.

1. In the website, create a new CSHTML file named *ListProductsForDelete.cshtml*.

2. Replace the existing markup with the following:

```
@{
  var db = Database.Open("SmallBakery");
  var selectQueryString = "SELECT * FROM Product ORDER BY Name";
}
<!DOCTYPE html>
<html>
<head>
    <title>Delete a Product</title>
    <style>
        table, th, td {
          border: solid 1px #bbbbbb;
          border-collapse: collapse;
          padding: 2px;
        }
     </style>
</head>
<body>
  <h1>Delete a Product</h1>
  <form method="post" action="" name="form">
    <table border="1">
      <thead>
        <tr>
          <th> </th>
          <th>Name</th>
          <th>Description</th>
          <th>Price</th>
        </tr>
      </thead>
      <tbody>
        @foreach (var row in db.Query(selectQueryString)) {
          <tr>
            <td><a href="@Href("~/DeleteProduct", row.Id)">Delete</a></td>
            <td>@row.Name</td>
            <td>@row.Description</td>
            <td>@row.Price</td>
          </tr>
        }
      </tbody>
    </table>
  </form>
</body>
</html>
```

This page is similar to the *EditProducts.cshtml* page from earlier. However, instead of displaying an **Edit** link for each product, it displays a **Delete** link. The **Delete** link is created using the following embedded code in the markup:

```
<a href="@Href("~/DeleteProduct", row.Id)">Delete</a>
```

This creates a URL that looks like this when users click the link:

`http://<server>/DeleteProduct/4`

The URL calls a page named *DeleteProduct.cshtml* (which you'll create next) and passes it the ID of the product to delete (here, 4).

3. Save the file, but leave it open.

4. Create another CHTML file named *DeleteProduct.cshtml*. Replace the existing content with the following:

```
@{
  var db = Database.Open("SmallBakery");
  var ProductId = UrlData[0];
  if (ProductId.IsEmpty()) {
    Response.Redirect("~/ListProductsForDelete");
  }
  var prod = db.QuerySingle("SELECT * FROM PRODUCT WHERE ID = @0", ProductId);
  if( IsPost && !ProductId.IsEmpty()) {
    var deleteQueryString = "DELETE FROM Product WHERE Id=@0";
    db.Execute(deleteQueryString, ProductId);
    Response.Redirect("~/ListProductsForDelete");
  }
}

<!DOCTYPE html>
<html>
<head>
    <title>Delete Product</title>
</head>
<body>
  <h1>Delete Product - Confirmation</h1>
  <form method="post" action="" name="form">
    <p>Are you sure you want to delete the following product?</p>

    <p>Name: @prod.Name <br />
       Description: @prod.Description <br />
       Price: @prod.Price</p>
    <p><input type="submit" value="Delete" /></p>
  </form>
</body>
</html>
```

This page is called by *ListProductsForDelete.cshtml* and lets users confirm that they want to delete a product. To list the product to be deleted, you get the ID of the product to delete from the URL using the following code:

```
var ProductId = UrlData[0];
```

The page then asks the user to click a button to actually delete the record. This is an important security measure: when you perform sensitive operations in your website like updating or deleting data, these operations should always be done using a POST operation, not a GET operation. If your site is set up so that a delete operation can be performed using a GET operation, anyone can pass a URL like `http://<server>/DeleteProduct/4` and delete anything they want from your database. By adding the confirmation and coding the page so that the deletion can be performed only by using a POST, you add a measure of security to your site.

The actual delete operation is performed using the following code, which first confirms that this is a post operation and that the ID isn't empty:

```
if( IsPost && !ProductId.IsEmpty()) {
    var deleteQueryString = "DELETE FROM Product WHERE Id=@0";
    db.Execute(deleteQueryString, ProductId);
    Response.Redirect("~/ListProductsForDelete");
}
```

The code runs a SQL statement that deletes the specified record and then redirects the user back to the listing page.

5. Run *ListProductsForDelete.cshtml* in a browser.

	Name	Description	Price
Delete	Apple Pie	Second only to your mom's pie.	12.99
Delete	Bread	Baked fresh every day.	2.99
Delete	Cherry Pie	Made with organic cherries from our garden.	8.99
Delete	Cupcakes	Your kids and the kid in you will love these.	7.99
Delete	Lemon Pie	Made with the best lemmons in the world.	11.99
Delete	Pecan Pie	If you like pecans this is fro you.	10.99
Delete	Strawberry Shortcake	Made with organic strawberries from our garden.	9.99

6. Click the **Delete** link for one of the products. The *DeleteProduct.cshtml* page is displayed to confirm that you want to delete that record.

7. Click the **Delete** button. The product record is deleted and the page is refreshed with an updated product listing.

TIP

Connecting to a Database

You can connect to a database in two ways. The first is to use the `Database.Open` method and to specify the name of the database file (less the *.sdf* extension):

```
var db = Database.Open("SmallBakery");
```

The `Open` method assumes that the *.sdf* file is in the website's *App_Data* folder. This folder is designed specifically for holding data. For example, it has appropriate permissions to allow the website to read and write data, and as a security measure, WebMatrix does not allow access to files from this folder.

The second way is to use a connection string. A connection string contains information about how to connect to a database. This can include a file path, or it can include the name of a SQL Server database on a local or remote server, along with a user name and password to connect to that server. (If you keep data in a centrally managed version of SQL Server, such as on a hosting provider's site, you always use a connection string to specify the database connection information.)

In WebMatrix, connection strings are usually stored in an XML file named *Web.config*. As the name implies, you can use a *Web.config* file in the root of your website to store the site's configuration information, including any connection strings that your site might require. An example of a connection string in a *Web.config* file might look like the following:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <connectionStrings>
   <add
     name="SQLServerConnectionString"
     connectionString= "server=myServer;database=myDatabase;uid=username;pwd=password"
     providerName="System.Data.SqlClient" />
  </connectionStrings>
</configuration>
```

In the example, the connection string points to a database in an instance of SQL Server that's running on a server somewhere (as opposed to a local *.sdf* file). You would need to substitute the appropriate names for `myServer` and `myDatabase`, and specify SQL Server login values for `username` and `password`. (The username and password values are not necessarily the same as your Windows credentials or as the values that your hosting provider has given you for logging in to their servers. Check with the administrator for the exact values you need.)

The `Database.Open` method is flexible, because it lets you pass either the name of a database *.sdf* file or the name of a connection string that's stored in the *Web.config* file. The following example shows how to connect to the database using the connection string illustrated in the previous example:

```
@{
    var db = Database.Open("SQLServerConnectionString");
}
```

As noted, the `Database.Open` method lets you pass either a database name or a connection string, and it'll figure out which to use. This is very useful when you deploy (publish) your website. You can use an *.sdf* file in the *App_Data* folder when you're developing and testing your site. Then when you move your site to a production server, you can use a connection string in the *Web.config* file that has the same name as your *.sdf* file but that points to the hosting provider's database — all without having to change your code.

Finally, if you want to work directly with a connection string, you can call the `Database.OpenConnectionString` method and pass it the actual connection string instead of just the name of one in the *Web.config* file. This might be useful in situations where for some reason you don't have access to the connection string (or values in it, such as the *.sdf* file name) until the page is running. However, for most scenarios, you can use `Database.Open` as described in this article.

Displaying Data in a Chart with ASP.NET Web Pages (Razor)

4/10/2020 • 20 minutes to read • Edit Online

by Microsoft

This article explains how to use a chart to display data in an ASP.NET Web Pages (Razor) website by using the `Chart` helper.

What you'll learn:

- How to display data in a chart.
- How to style charts using built-in themes.
- How to save charts and how to cache them for better performance.

These are the ASP.NET programming features introduced in the article:

- The `Chart` helper.

> **NOTE**
>
> The information in this article applies to ASP.NET Web Pages 1.0 and Web Pages 2.

The Chart Helper

When you want to display your data in graphical form, you can use `Chart` helper. The `Chart` helper can render an image that displays data in a variety of chart types. It supports many options for formatting and labeling. The `Chart` helper can render more than 30 types of charts, including all the types of charts that you might be familiar with from Microsoft Excel or other tools — area charts, bar charts, column charts, line charts, and pie charts, along with more specialized charts like stock charts.

AREA CHART

BAR CHART

Column chart

Line chart

AREA CHART

BAR CHART

Pie chart

Stock chart

Chart Elements

Charts show data and additional elements like legends, axes, series, and so on. The following picture shows many of the chart elements that you can customize when you use the `Chart` helper. This article shows you how to set some (not all) of these elements.

Creating a Chart from Data

The data you display in a chart can be from an array, from the results returned from a database, or from data that's in an XML file.

Using an Array

As explained in Introduction to ASP.NET Web Pages Programming Using the Razor Syntax, an array lets you store a collection of similar items in a single variable. You can use arrays to contain the data that you want to include in your chart.

This procedure shows how you can create a chart from data in arrays, using the default chart type. It also shows how to display the chart within the page.

1. Create a new file named *ChartArrayBasic.cshtml*.
2. Replace the existing content with the following:

```
@{
    var myChart = new Chart(width: 600, height: 400)
        .AddTitle("Chart Title")
        .AddSeries(
            name: "Employee",
            xValue: new[] {  "Peter", "Andrew", "Julie", "Mary", "Dave" },
            yValues: new[] { "2", "6", "4", "5", "3" })
        .Write();
}
```

The code first creates a new chart and sets its width and height. You specify the chart title by using the `AddTitle` method. To add data, you use the `AddSeries` method. In this example, you use the `name`, `xValue`, and `yValues` parameters of the `AddSeries` method. The `name` parameter is displayed in the chart legend. The `xValue` parameter contains an array of data that's displayed along the horizontal axis of the chart. The `yValues` parameter contains an array of data that's used to plot the vertical points of the chart.

The `Write` method actually renders the chart. In this case, because you didn't specify a chart type, the `Chart` helper renders its default chart, which is a column chart.

3. Run the page in the browser. The browser displays the chart.

Using a Database Query for Chart Data

If the information you want to chart is in a database, you can run a database query and then use data from the results to create the chart. This procedure shows you how to read and display the data from the database created in the article Introduction to Working with a Database in ASP.NET Web Pages Sites.

1. Add an *App_Data* folder to the root of the website if the folder does not already exist.

2. In the *App_Data* folder, add the database file named *SmallBakery.sdf* that's described in Introduction to Working with a Database in ASP.NET Web Pages Sites.

3. Create a new file named *ChartDataQuery.cshtml*.

4. Replace the existing content with the following:

```
@{
    var db = Database.Open("SmallBakery");
    var data = db.Query("SELECT Name, Price FROM Product");
    var myChart = new Chart(width: 600, height: 400)
        .AddTitle("Product Sales")
        .DataBindTable(dataSource: data, xField: "Name")
        .Write();
}
```

The code first opens the SmallBakery database and assigns it to a variable named `db`. This variable

represents a `Database` object that can be used to read from and write to the database. Next, the code runs a SQL query to get the name and price of each product. The code creates a new chart and passes the database query to it by calling the chart's `DataBindTable` method. This method takes two parameters: the `dataSource` parameter is for the data from the query, and the `xField` parameter lets you set which data column is used for the chart's x-axis.

As an alternative to using the `DataBindTable` method, you can use the `AddSeries` method of the `Chart` helper. The `AddSeries` method lets you set the `xValue` and `yValues` parameters. For example, instead of using the `DataBindTable` method like this:

```
.DataBindTable(data, "Name")
```

You can use the `AddSeries` method like this:

```
.AddSeries("Default",
    xValue: data, xField: "Name",
    yValues: data, yFields: "Price")
```

Both render the same results. The `AddSeries` method is more flexible because you can specify the chart type and data more explicitly, but the `DataBindTable` method is easier to use if you don't need the extra flexibility.

5. Run the page in a browser.

Using XML Data

The third option for charting is to use an XML file as the data for the chart. This requires that the XML file also have a schema file (*.xsd* file) that describes the XML structure. This procedure shows you how to read data from an XML file.

1. In the *App_Data* folder, create a new XML file named *data.xml*.

2. Replace the existing XML with the following, which is some XML data about employees in a fictional company.

```
<?xml version="1.0" standalone="yes" ?>
<NewDataSet xmlns="http://tempuri.org/data.xsd">
    <Employee>
        <Name>Erin</Name>
        <Sales>10440</Sales>
    </Employee>
    <Employee>
        <Name>Kim</Name>
        <Sales>17772</Sales>
    </Employee>
    <Employee>
        <Name>Dean</Name>
        <Sales>23880</Sales>
    </Employee>
    <Employee>
        <Name>David</Name>
        <Sales>7663</Sales>
    </Employee>
    <Employee>
        <Name>Sanjay</Name>
        <Sales>21773</Sales>
    </Employee>
    <Employee>
        <Name>Michelle</Name>
        <Sales>32294</Sales>
    </Employee>
</NewDataSet>
```

3. In the *App_Data* folder, create a new XML file named *data.xsd*. (Note that the extension this time is *.xsd*.)

4. Replace the existing XML with the following:

```
<?xml version="1.0" ?>
```

This example also shows you how to specify a particular chart type. When the data is added in the `AddSeries` method, the `chartType` parameter is also set to display a pie chart.

7. Run the page in a browser.

TIP

"Using" Statements and Fully Qualified Names

The .NET Framework that ASP.NET Web Pages with Razor syntax is based on consists of many thousands of components (classes). To make it manageable to work with all these classes, they're organized into *namespaces*, which are somewhat like libraries. For example, the `System.Web` namespace contains classes that support browser/server communication, the `System.Xml` namespace contains classes that are used to create and read XML files, and the `System.Data` namespace contains classes that let you work with data.

In order to access any given class in the .NET Framework, code needs to know not just the class name, but also the namespace that the class is in. For example, in order to use the `Chart` helper, code needs to find the `System.Web.Helpers.Chart` class, which combines the namespace (`System.Web.Helpers`) with the class name (`Chart`). This is known as the class's *fully-qualified* name — its complete, unambiguous location within the vastness of the .NET Framework. In code, this would look like the following:

```
var myChart = new System.Web.Helpers.Chart(width: 600, height: 400) // etc.
```

However, it's cumbersome (and error prone) to have to use these long, fully-qualified names every time you want to refer to a class or helper. Therefore, to make it easier to use class names, you can *import* the namespaces you're interested in, which is usually is just a handful from among the many namespaces in the .NET Framework. If you've imported a namespace, you can use just a class name (`Chart`) instead of the fully qualified name (`System.Web.Helpers.Chart`). When your code runs and encounters a class name, it can look in just the namespaces you've imported to find that class.

When you use ASP.NET Web Pages with Razor syntax to create web pages, you typically use the same set of classes each time, including the `WebPage` class, the various helpers, and so on. To save you the work of importing the relevant namespaces every time you create a website, ASP.NET is configured so it automatically imports a set of core namespaces for every website. That's why you haven't had to deal with namespaces or importing up to now; all the classes you've worked with are in namespaces that are already imported for you.

However, sometimes you need to work with a class that isn't in a namespace that's automatically imported for you. In that case, you can either use that class's fully-qualified name, or you can manually import the namespace that contains the class. To import a namespace, you use the `using` statement (`import` in Visual Basic), as you saw in an example earlier the article.

For example, the `DataSet` class is in the `System.Data` namespace. The `System.Data` namespace is not automatically available to ASP.NET Razor pages. Therefore, to work with the `DataSet` class using its fully qualified name, you can use code like this:

```
var dataSet = new System.Data.DataSet();
```

If you have to use the `DataSet` class repeatedly you can import a namespace like this and then use just the class name in code:

```
@using System.Data;
@{
    var dataSet = new DataSet();
    // etc.
}
```

You can add `using` statements for any other .NET Framework namespaces that you want to reference. However, as noted, you won't need to do this often, because most of the classes that you'll work with are in namespaces that are imported automatically by ASP.NET for use in *.cshtml* and *.vbhtml* pages.

Displaying Charts Inside a Web Page

In the examples you've seen so far, you create a chart and then the chart is rendered directly to the browser as a graphic. In many cases, though, you want to display a chart as part of a page, not just by itself in the browser. To do that requires a two-step process. The first step is to create a page that generates the chart, as you've already seen.

The second step is to display the resulting image in another page. To display the image, you use an HTML `<img>` element, in the same way you would to display any image. However, instead of referencing a *.jpg* or *.png* file, the `<img>` element references the *.cshtml* file that contains the `Chart` helper that creates the chart. When the display page runs, the `<img>` element gets the output of the `Chart` helper and renders the chart.

1. Create a file named *ShowChart.cshtml*.

2. Replace the existing content with the following:

```
<!DOCTYPE html>
<html>
  <head>
    <title>Chart Example</title>
  </head>
  <body>
    <h1>Chart Example</h1>
    <p>The following chart is generated by the <em>ChartArrayBasic.cshtml</em> file, but is shown
       in this page.</p>
    <p><img src="ChartArrayBasic.cshtml" /> </p>
  </body>
</html>
```

   The code uses the `<img>` element to display the chart that you created earlier in the *ChartArrayBasic.cshtml* file.

3. Run the web page in a browser. The *ShowChart.cshtml* file displays the chart image based on the code contained in the *ChartArrayBasic.cshtml* file.

Styling a Chart

The `Chart` helper supports a large number of options that let you customize the appearance of the chart. You can set colors, fonts, borders, and so on. An easy way to customize the appearance of a chart is to use a *theme*. Themes are collections of information that specify how to render a chart using fonts, colors, labels, palettes, borders, and effects. (Note that the style of a chart does not indicate the type of chart.)

The following table lists built-in themes.

THEME	DESCRIPTION
`Vanilla`	Displays red columns on a white background.

THEME	DESCRIPTION
`Blue`	Displays blue columns on a blue gradient background.
`Green`	Displays blue columns on a green gradient background.
`Yellow`	Displays orange columns on a yellow gradient background.
`Vanilla3D`	Displays 3-D red columns on a white background.

You can specify the theme to use when you create a new chart.

1. Create a new file named *ChartStyleGreen.cshtml*.

2. Replace the existing content in the page with the following:

```
@{
    var db = Database.Open("SmallBakery");
    var data = db.Query("SELECT Name, Price FROM Product");
    var myChart = new Chart(width: 600,
                        height: 400,
                        theme: ChartTheme.Green)
        .AddTitle("Product Sales")
        .DataBindTable(data, "Name")
        .Write();
}
```

   This code is the same as the earlier example that uses the database for data, but adds the `theme` parameter when it creates the `Chart` object. The following shows the changed code:

```
var myChart = new Chart(width: 600,
                    height: 400,
                    theme: ChartTheme.Green)
```

3. Run the page in a browser. You see the same data as before, but the chart looks more polished:

Saving a Chart

When you use the `Chart` helper as you've seen so far in this article, the helper re-creates the chart from scratch each time it's invoked. If necessary, the code for the chart also re-queries the database or re-reads the XML file to get the data. In some cases, doing this can be a complex operation, such as if the database that you're querying is large, or if the XML file contains a lot of data. Even if the chart doesn't involve a lot of data, the process of dynamically creating an image takes up server resources, and if many people request the page or pages that display the chart, there can be an impact on the performance of your website.

To help you reduce the potential performance impact of creating a chart, you can create a chart the first time you need it and then save it. When the chart is needed again, rather than regenerating it, you can just fetch the saved version and render that.

You can save a chart in these ways:

- Cache the chart in computer memory (on the server).
- Save the chart as an image file.
- Save the chart as an XML file. This option lets you modify the chart before you save it.

Caching a Chart

After you've created a chart, you can cache it. Caching a chart means that it doesn't have to be re-created if it needs to be displayed again. When you save a chart in the cache, you give it a key that must be unique to that chart.

Charts saved to the cache might be removed if the server runs low on memory. In addition, the cache is cleared if your application restarts for any reason. Therefore, the standard way to work with a cached chart is to always check first whether it's available in the cache, and if not, then to create or re-create it.

1. At the root of your website, create a file named *ShowCachedChart.cshtml*.

2. Replace the existing content with the following:

```
<!DOCTYPE html>
<html>
    <head>
        <title>Chart Example</title>
    </head>
<body>
    <h1>Chart Example</h1>
    <img src="ChartSaveToCache.cshtml?key=myChartKey" />
    <p><a href="ClearCache.cshtml">Clear cache</a></p>
</body>
</html>
```

   The `<img>` tag includes a `src` attribute that points to the *ChartSaveToCache.cshtml* file and passes a key to the page as a query string. The key contains the value "myChartKey". The *ChartSaveToCache.cshtml* file contains the `Chart` helper that creates the chart. You'll create this page in a moment.

   At the end of the page there's a link to a page named *ClearCache.cshtml*. That's a page that you'll also create shortly. You need the *ClearCache.cshtml* only to test caching for this example — it's not a link or page that you'd normally include when working with cached charts.

3. At the root of your website, create a new file named *ChartSaveToCache.cshtml*.

4. Replace the existing content with the following:

```
@{
    var chartKey = Request["key"];
    if (chartKey != null) {
        var cachedChart = Chart.GetFromCache(key: chartKey);
        if (cachedChart == null) {
            cachedChart = new Chart(600, 400);
            cachedChart.AddTitle("Cached Chart -- Cached at " + DateTime.Now);
            cachedChart.AddSeries(
               name: "Employee",
               axisLabel: "Name",
               xValue: new[] { "Peter", "Andrew", "Julie", "Mary", "Dave" },
               yValues: new[] { "2", "6", "4", "5", "3" });
            cachedChart.SaveToCache(key: chartKey,
               minutesToCache: 2,
               slidingExpiration: false);
        }
        Chart.WriteFromCache(chartKey);
    }
}
```

The code first checks whether anything was passed as the key value in the query string. If so, the code tries to read a chart out of the cache by calling the `GetFromCache` method and passing it the key. If it turns out that there's nothing in the cache under that key (which would happen the first time that the chart is requested), the code creates the chart as usual. When the chart is finished, the code saves it to the cache by calling `SaveToCache`. That method requires a key (so the chart can be requested later), and the amount of time that the chart should be saved in the cache. (The exact time you'd cache a chart would depend on how often you thought the data it represents might change.) The `SaveToCache` method also requires a `slidingExpiration` parameter — if this is set to true, the timeout counter is reset each time the chart is accessed. In this case, it in effect means that the chart's cache entry expires 2 minutes after the last time someone accessed the chart. (The alternative to sliding expiration is absolute expiration, meaning that the cache entry would expire exactly 2 minutes after it was put into the cache, no matter how often it had been accessed.)

Finally, the code uses the `WriteFromCache` method to fetch and render the chart from the cache. Note that this method is outside the `if` block that checks the cache, because it will get the chart from the cache whether the chart was there to begin with or had to be generated and saved in the cache.

Notice that in the example, the `AddTitle` method includes a timestamp. (It adds the current date and time — `DateTime.Now` — to the title.)

5. Create a new page named *ClearCache.cshtml* and replace its content with the following:

```
@{
    WebCache.Remove("myChartKey");
}
<!DOCTYPE html>
<html lang="en">
  <body>
    <p>Cache has been cleared.</p>
    <p>Return to <a href="ShowCachedChart.cshtml">ShowCachedChart.cshtml</a></p>
  </body>
</html>
```

This page uses the `WebCache` helper to remove the chart that's cached in *ChartSaveToCache.cshtml*. As noted earlier, you don't normally have to have a page like this. You're creating it here only to make it easier to test caching.

6. Run the *ShowCachedChart.cshtml* web page in a browser. The page displays the chart image based on the code contained in the *ChartSaveToCache.cshtml* file. Take note of what the timestamp says in the chart title.

7. Close the browser.

8. Run the *ShowCachedChart.cshtml* again. Notice that the timestamp is the same as before, which indicates that the chart was not regenerated, but was instead read from the cache.

9. In *ShowCachedChart.cshtml*, click the **Clear cache** link. This takes you to *ClearCache.cshtml*, which reports that the cache has been cleared.

10. Click the **Return to ShowCachedChart.cshtml** link, or re-run *ShowCachedChart.cshtml* from WebMatrix. Notice that this time the timestamp has changed, because the cache has been cleared. Therefore, the code had to regenerate the chart and put it back into the cache.

Saving a Chart as an Image File

You can also save a chart as an image file (for example, as a *.jpg* file) on the server. You can then use the image file the way you would any image. The advantage is the file is stored rather than saved to a temporary cache. You can save a new chart image at different times (for example, every hour) and then keep a permanent record of the changes that occur over time. Note that you must make sure that your web application has permission to save a file to the folder on the server where you want to put the image file.

1. At the root of your website, create a folder named *_ChartFiles* if it does not already exist.

2. At the root of your website, create a new file named *ChartSave.cshtml*.

3. Replace the existing content with the following:

```
@{
    var filePathName = "_ChartFiles/chart01.jpg";
    if (!File.Exists(Server.MapPath(filePathName))) {
        var chartImage = new Chart(600, 400);
        chartImage.AddTitle("Chart Title");
        chartImage.AddSeries(
                name: "Employee",
                axisLabel: "Name",
                xValue: new[] {  "Peter", "Andrew", "Julie", "Mary", "Dave" },
                yValues: new[] { "2", "6", "4", "5", "3" });
        chartImage.Save(path: filePathName);
    }
}
<!DOCTYPE html>
<html>
    <head>
        <title>Chart Example</title>
    </head>
    <body>
        <img src="@filePathName" />
    </body>
</html>
```

The code first checks to see whether the *.jpg* file exists by calling the `File.Exists` method. If the file does not exist, the code creates a new `Chart` from an array. This time, the code calls the `Save` method and passes the `path` parameter to specify the file path and file name of where to save the chart. In the body of the page, an `<img>` element uses the path to point to the *.jpg* file to display.

4. Run the *ChartSave.cshtml* file.

5. Return to WebMatrix. Notice that an image file named *chart01.jpg* has been saved in the *_ChartFiles* folder.

Saving a Chart as an XML File

Finally, you can save a chart as an XML file on the server. An advantage of using this method over caching the chart or saving the chart to a file is that you could modify the XML before displaying the chart if you wanted to. Your application has to have read/write permissions for the folder on the server where you want to put the image file.

1. At the root of your website, create a new file named *ChartSaveXml.cshtml*.

2. Replace the existing content with the following:

```
@{
    Chart chartXml;
    var filePathName = "_ChartFiles/XmlChart.xml";
    if (File.Exists(Server.MapPath(filePathName))) {
        chartXml = new Chart(width: 600,
                             height: 400,
                             themePath: filePathName);
    }
    else {
        chartXml = new Chart(width: 600,
                             height: 400);
        chartXml.AddTitle("Chart Title -- Saved at " + DateTime.Now);
        chartXml.AddSeries(
            name: "Employee",
            axisLabel: "Name",
            xValue: new[] { "Peter", "Andrew", "Julie", "Mary", "Dave" },
            yValues: new[] { "2", "6", "4", "5", "3" });
        chartXml.SaveXml(path: filePathName);
    }
    chartXml.Write();
}
```

This code is similar to the code that you saw earlier for storing a chart in the cache, except that it uses an XML file. The code first checks to see whether the XML file exists by calling the `File.Exists` method. If the file does exist, the code creates a new `Chart` object and passes the file name as the `themePath` parameter. This creates the chart based on whatever's in the XML file. If the XML file doesn't already exist, the code creates a chart like normal and then calls `SaveXml` to save it. The chart is rendered using the `Write` method, as you've seen before.

As with the page that showed caching, this code includes a timestamp in the chart title.

3. Create a new page named *ChartDisplayXMLChart.cshtml* and add the following markup to it:

```
<!DOCTYPE html>
<html>
  <head>
    <meta charset="utf-8" />
    <title>Display chart from XML</title>
  </head>
  <body>
    <img src="ChartSaveXML.cshtml" />
  </body>
</html>
```

4. Run the *ChartDisplayXMLChart.cshtml* page. The chart is displayed. Take note of the timestamp in the chart's title.

5. Close the browser.

6. In WebMatrix, right-click the *_ChartFiles* folder, click **Refresh**, and then open the folder. The *XMLChart.xml* file in this folder was created by the `Chart` helper.

7. Run the *ChartDisplayXMLChart.cshtml* page again. The chart shows the same timestamp as the first time you ran the page. That's because the chart is being generated from the XML you saved earlier.

8. In WebMatrix, open the *_ChartFiles* folder and delete the *XMLChart.xml* file.

9. Run the *ChartDisplayXMLChart.cshtml* page once more. This time, the timestamp is updated, because the `Chart` helper had to recreate the XML file. If you want, check the *_ChartFiles* folder and notice that the XML file is back.

Working with Files in an ASP.NET Web Pages (Razor) Site

2/20/2020 • 16 minutes to read • Edit Online

by Tom FitzMacken

This article explains how to read, write, append, delete, and upload files in an ASP.NET Web Pages (Razor) site.

> **NOTE**
> If you want to upload images and manipulate them (for example, flip or resize them), see Working with Images in an ASP.NET Web Pages Site.

What you'll learn:

- How to create a text file and write data to it.
- How to append data to an existing file.
- How to read a file and display from it.
- How to delete files from a website.
- How to let users upload one file or multiple files.

These are the ASP.NET programming features introduced in the article:

- The `File` object, which provides a way to manage files.
- The `FileUpload` helper.
- The `Path` object, which provides methods that let you manipulate path and file names.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- WebMatrix 2

This tutorial also works with WebMatrix 3.

Creating a Text File and Writing Data to It

In addition to using a database in your website, you might work with files. For example, you might use text files as a simple way to store data for the site. (A text file that's used to store data is sometimes called a *flat file*.) Text files can be in different formats, like *.txt*, *.xml*, or *.csv* (comma-delimited values).

If you want to store data in a text file, you can use the `File.WriteAllText` method to specify the file to create and the data to write to it. In this procedure, you'll create a page that contains a simple form with three `input` elements (first name, last name, and email address) and a **Submit** button. When the user submits the form, you'll store the user's input in a text file.

1. Create a new folder named *App_Data*, if it doesn't exist already.

2. At the root of your website, create a new file named *UserData.cshtml*.

3. Replace the existing content with the following:

```
@{
    var result = "";
    if (IsPost)
    {
        var firstName = Request["FirstName"];
        var lastName = Request["LastName"];
        var email = Request["Email"];

        var userData = firstName + "," + lastName +
            "," + email + Environment.NewLine;

        var dataFile = Server.MapPath("~/App_Data/data.txt");
        File.WriteAllText(@dataFile, userData);
        result = "Information saved.";
    }
}
<!DOCTYPE html>
<html>
<head>
    <title>Write Data to a File</title>
</head>
<body>
    <form id="form1" method="post">
    <div>
        <table>
            <tr>
                <td>First Name:</td>
                <td><input id="FirstName" name="FirstName" type="text" /></td>

            </tr>
            <tr>
                <td>Last Name:</td>
                <td><input id="LastName" name="LastName" type="text" /></td>
            </tr>
            <tr>
                <td>Email:</td>
                <td><input id="Email" name="Email" type="text" /></td>
            </tr>
            <tr>
                <td></td>
                <td><input type="submit" value="Submit"/></td>
            </tr>
        </table>
    </div>
    <div>
    @if(result != ""){
        <p>Result: @result</p>
    }
    </div>
    </form>
</body>
</html>
```

The HTML markup creates the form with the three text boxes. In the code, you use the `IsPost` property to determine whether the page has been submitted before you start processing.

The first task is to get the user input and assign it to variables. The code then concatenates the values of the separate variables into one comma-delimited string, which is then stored in a different variable. Notice that the comma separator is a string contained in quotation marks (","), because you're literally embedding a comma into the big string that you're creating. At the end of the data that you concatenate together, you add `Environment.NewLine`. This adds a line break (a newline character). What you're creating with all this concatenation is a string that looks like this:

```
David,Jones,davidj@contoso.com
```

(With an invisible line break at the end.)

You then create a variable (`dataFile`) that contains the location and name of the file to store the data in. Setting the location requires some special handling. In websites, it's a bad practice to refer in code to absolute paths like *C:\Folder\File.txt* for files on the web server. If a website is moved, an absolute path will be wrong. Moreover, for a hosted site (as opposed to on your own computer) you typically don't even know what the correct path is when you're writing the code.

But sometimes (like now, for writing a file) you do need a complete path. The solution is to use the `MapPath` method of the `Server` object. This returns the complete path to your website. To get the path for the website root, you user the `~` operator (to represen the site's virtual root) to `MapPath`. (You can also pass a subfolder name to it, like *~/App_Data/*, to get the path for that subfolder.) You can then concatenate additional information onto whatever the method returns in order to create a complete path. In this example, you add a file name. (You can read more about how to work with file and folder paths in Introduction to ASP.NET Web Pages Programming Using the Razor Syntax.)

The file is saved in the *App_Data* folder. This folder is a special folder in ASP.NET that's used to store data files, as described in Introduction to Working with a Database in ASP.NET Web Pages Sites.

The `WriteAllText` method of the `File` object writes the data to the file. This method takes two parameters: the name (with path) of the file to write to, and the actual data to write. Notice that the name of the first parameter has an `@` character as a prefix. This tells ASP.NET that you're providing a verbatim string literal, and that characters like "/" should not be interpreted in special ways. (For more information, see Introduction to ASP.NET Web Programming Using the Razor Syntax.)

> **NOTE**
> In order for your code to save files in the *App_Data* folder, the application needs read-write permissions for that folder. On your development computer this is not typically an issue. However, when you publish your site to a hosting provider's web server, you might need to explicitly set those permissions. If you run this code on a hosting provider's server and get errors, check with the hosting provider to find out how to set those permissions.

- Run the page in a browser.

- Enter values into the fields and then click **Submit**.
- Close the browser.
- Return to the project and refresh the view.
- Open the *data.txt* file. The data you submitted in the form is in the file.

```
data.txt    UserData.cshtml
1 David,Jones,davidj@contoso.com
2
```

- Close the *data.txt* file.

Appending Data to an Existing File

In the previous example, you used `WriteAllText` to create a text file that's got just one piece of data in it. If you call the method again and pass it the same file name, the existing file is completely overwritten. However, after you've created a file you often want to add new data to the end of the file. You can do that using the `AppendAllText` method of the `File` object.

1. In the website, make a copy of the *UserData.cshtml* file and name the copy *UserDataMultiple.cshtml*.

2. Replace the code block before the opening `<!DOCTYPE html>` tag with the following code block:

```
@{
    var result = "";
    if (IsPost)
    {
        var firstName = Request["FirstName"];
        var lastName = Request["LastName"];
        var email = Request["Email"];

        var userData = firstName + "," + lastName +
            "," + email + Environment.NewLine;

        var dataFile = Server.MapPath("~/App_Data/data.txt");
        File.AppendAllText (@dataFile, userData);
        result = "Information saved.";
    }
}
```

   This code has one change in it from the previous example. Instead of using `WriteAllText`, it uses `the AppendAllText` method. The methods are similar, except that `AppendAllText` adds the data to the end of the file. As with `WriteAllText`, `AppendAllText` creates the file if it doesn't already exist.

3. Run the page in a browser.

4. Enter values for the fields and then click **Submit**.

5. Add more data and submit the form again.

6. Return to your project, right-click the project folder, and then click **Refresh**.

7. Open the *data.txt* file. It now contains the new data that you just entered.

```
data.txt    UserDataMultiple.cshtml
1 David,Jones,davidj@contoso.com
2 Jim,Hance,jimh@contoso.com
3
```

Reading and Displaying Data from a File

Even if you don't need to write data to a text file, you'll probably sometimes need to read data from one. To do this, you can again use the `File` object. You can use the `File` object to read each line individually (separated by line breaks) or to read individual item no matter how they're separated.

This procedure shows you how to read and display the data that you created in the previous example.

1. At the root of your website, create a new file named *DisplayData.cshtml*.
2. Replace the existing content with the following:

```
@{
    var result = "";
    Array userData = null;
    char[] delimiterChar = {','};

    var dataFile = Server.MapPath("~/App_Data/data.txt");

    if (File.Exists(dataFile)) {
        userData = File.ReadAllLines(dataFile);
        if (userData == null) {
            // Empty file.
            result = "The file is empty.";
        }
    }
    else {
        // File does not exist.
        result = "The file does not exist.";
    }
}
<!DOCTYPE html>

<html>
<head>
    <title>Reading Data from a File</title>
</head>
<body>
    <div>
        <h1>Reading Data from a File</h1>
        @result
        @if (result == "") {
            <ol>
            @foreach (string dataLine in userData) {
            <li>
                User
                <ul>
                @foreach (string dataItem in dataLine.Split(delimiterChar)) {
                    <li>@dataItem</li >
                }
                </ul>
            </li>
            }
            </ol>
        }
    </div>
</body>
</html>
```

The code starts by reading the file that you created in the previous example into a variable named `userData`, using this method call:

```
File.ReadAllLines(dataFile)
```

The code to do this is inside an `if` statement. When you want to read a file, it's a good idea to use the `File.Exists` method to determine first whether the file is available. The code also checks whether the file is empty.

The body of the page contains two `foreach` loops, one nested inside the other. The outer `foreach` loop gets one line at a time from the data file. In this case, the lines are defined by line breaks in the file — that is, each data item is on its own line. The outer loop creates a new item (`<li>` element) inside an ordered list (

`<ol>` element).

The inner loop splits each data line into items (fields) using a comma as a delimiter. (Based on the previous example, this means that each line contains three fields — the first name, last name, and email address, each separated by a comma.) The inner loop also creates a `<ul>` list and displays one list item for each field in the data line.

The code illustrates how to use two data types, an array and the `char` data type. The array is required because the `File.ReadAllLines` method returns data as an array. The `char` data type is required because the `Split` method returns an `array` in which each element is of the type `char`. (For information about arrays, see Introduction to ASP.NET Web Programming Using the Razor Syntax.)

3. Run the page in a browser. The data you entered for the previous examples is displayed.

TIP

Displaying Data from a Microsoft Excel Comma-Delimited File

You can use Microsoft Excel to save the data contained in a spreadsheet as a comma-delimited file (*.csv* file). When you do, the file is saved in plain text, not in Excel format. Each row in the spreadsheet is separated by a line break in the text file, and each data item is separated by a comma. You can use the code shown in the previous example to read an Excel comma-delimited file just by changing the name of the data file in your code.

Deleting Files

To delete files from your website, you can use the `File.Delete` method. This procedure shows how to let users delete an image (*.jpg* file) from an *images* folder if they know the name of the file.

NOTE

Important In a production website, you typically restrict who's allowed to make changes to the data. For information about how to set up membership and about ways to authorize users to perform tasks on the site, see Adding Security and Membership to an ASP.NET Web Pages Site.

1. In the website, create a subfolder named *images*.
2. Copy one or more *.jpg* files into the *images* folder.
3. In the root of the website, create a new file named *FileDelete.cshtml*.
4. Replace the existing content with the following:

```
@{
    bool deleteSuccess = false;
    var photoName = "";
    if (IsPost) {
        photoName = Request["photoFileName"] + ".jpg";
        var fullPath = Server.MapPath("~/images/" + photoName);

        if (File.Exists(fullPath))
        {
                File.Delete(fullPath);
                deleteSuccess = true;
        }
    }
}
<!DOCTYPE html>
<html>
  <head>
    <title>Delete a Photo</title>
  </head>
  <body>
    <h1>Delete a Photo from the Site</h1>
    <form name="deletePhoto" action="" method="post">
      <p>File name of image to delete (without .jpg extension):
      <input name="photoFileName" type="text" value="" />
      </p>
      <p><input type="submit" value="Submit" /></p>
    </form>

    @if(deleteSuccess) {
        <p>
        @photoName deleted!
        </p>
        }
  </body>
</html>
```

This page contains a form where users can enter the name of an image file. They don't enter the *.jpg* file-name extension; by restricting the file name like this, you help prevents users from deleting arbitrary files on your site.

The code reads the file name that the user has entered and then constructs a complete path. To create the path, the code uses the current website path (as returned by the `Server.MapPath` method), the *images* folder name, the name that the user has provided, and ".jpg" as a literal string.

To delete the file, the code calls the `File.Delete` method, passing it the full path that you just constructed. At the end of the markup, code displays a confirmation message that the file was deleted.

5. Run the page in a browser.

6. Enter the name of the file to delete and then click **Submit**. If the file was deleted, the name of the file is displayed at the bottom of the page.

Letting Users Upload a File

The `FileUpload` helper lets users upload files to your website. The procedure below shows you how to let users upload a single file.

1. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you didn't add it previously.

2. In the *App_Data* folder, create a new a folder and name it *UploadedFiles*.

3. In the root, create a new file named *FileUpload.cshtml*.

4. Replace the existing content in the page with the following:

```
@using Microsoft.Web.Helpers;
@{
    var fileName = "";
    if (IsPost) {
        var fileSavePath = "";
        var uploadedFile = Request.Files[0];
        fileName = Path.GetFileName(uploadedFile.FileName);
        fileSavePath = Server.MapPath("~/App_Data/UploadedFiles/" +
          fileName);
        uploadedFile.SaveAs(fileSavePath);
    }
}
<!DOCTYPE html>
<html>
    <head>
    <title>FileUpload - Single-File Example</title>
    </head>
    <body>
    <h1>FileUpload - Single-File Example</h1>
    @FileUpload.GetHtml(
        initialNumberOfFiles:1,
        allowMoreFilesToBeAdded:false,
        includeFormTag:true,
        uploadText:"Upload")
    @if (IsPost) {
        <span>File uploaded!</span><br/>
    }
    </body>
</html>
```

The body portion of the page uses the `FileUpload` helper to create the upload box and buttons that you're probably familiar with:

The properties that you set for the `FileUpload` helper specify that you want a single box for the file to upload and that you want the submit button to read **Upload**. (You'll add more boxes later in the article.)

When the user clicks **Upload**, the code at the top of the page gets the file and saves it. The `Request` object that you normally use to get values from form fields also has a `Files` array that contains the file (or files) that have been uploaded. You can get individual files out of specific positions in the array — for example, to get the first uploaded file, you get `Request.Files[0]`, to get the second file, you get `Request.Files[1]`, and so on. (Remember that in programming, counting usually starts at zero.)

When you fetch an uploaded file, you put it in a variable (here, `uploadedFile`) so that you can manipulate it. To determine the name of the uploaded file, you just get its `FileName` property. However, when the user uploads a file, `FileName` contains the user's original name, which includes the entire path. It might look like this:

C:\Users\Public\Sample.txt

You don't want all that path information, though, because that's the path on the user's computer, not for your server. You just want the actual file name (*Sample.txt*). You can strip out just the file from a path by using the `Path.GetFileName` method, like this:

```
Path.GetFileName(uploadedFile.FileName)
```

The `Path` object is a utility that has a number of methods like this that you can use to strip paths, combine paths, and so on.

Once you've gotten the name of the uploaded file, you can build a new path for where you want to store the uploaded file in your website. In this case, you combine `Server.MapPath`, the folder names (*App_Data/UploadedFiles*), and the newly stripped file name to create a new path. You can then call the uploaded file's `SaveAs` method to actually save the file.

5. Run the page in a browser.

6. Click **Browse** and then select a file to upload.

The text box next to the **Browse** button will contain the path and file location.

7. Click **Upload**.

8. In the website, right-click the project folder and then click **Refresh**.

9. Open the *UploadedFiles* folder. The file that you uploaded is in the folder.

Letting Users Upload Multiple Files

In the previous example, you let users upload one file. But you can use the `FileUpload` helper to upload more than one file at a time. This is handy for scenarios like uploading photos, where uploading one file at a time is tedious. (You can read about uploading photos in Working with Images in an ASP.NET Web Pages Site.) This example shows how to let users upload two at a time, although you can use the same technique to upload more than that.

1. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already.

2. Create a new page named *FileUploadMultiple.cshtml*.

3. Replace the existing content in the page with the following:

```
@using Microsoft.Web.Helpers;
@{
  var message = "";
  if (IsPost) {
      var fileName = "";
      var fileSavePath = "";
      int numFiles = Request.Files.Count;
      int uploadedCount = 0;
      for(int i =0; i < numFiles; i++) {
          var uploadedFile = Request.Files[i];
          if (uploadedFile.ContentLength > 0) {
              fileName = Path.GetFileName(uploadedFile.FileName);
              fileSavePath = Server.MapPath("~/App_Data/UploadedFiles/" +
                fileName);
              uploadedFile.SaveAs(fileSavePath);
              uploadedCount++;
          }
       }
       message = "File upload complete. Total files uploaded: " +
         uploadedCount.ToString();
   }
}
<!DOCTYPE html>
<html>
    <head><title>FileUpload - Multiple File Example</title></head>
<body>
    <form id="myForm" method="post"
       enctype="multipart/form-data"
       action="">
    <div>
    <h1>File Upload - Multiple-File Example</h1>
    @if (!IsPost) {
        @FileUpload.GetHtml(
            initialNumberOfFiles:2,
            allowMoreFilesToBeAdded:true,
            includeFormTag:true,
            addText:"Add another file",
            uploadText:"Upload")
        }
    <span>@message</span>
    </div>
    </form>
</body>
</html>
```

In this example, the `FileUpload` helper in the body of the page is configured to let users upload two files by default. Because `allowMoreFilesToBeAdded` is set to `true`, the helper renders a link that lets user add more upload boxes:

To process the files that the user uploads, the code uses the same basic technique that you used in the previous example — get a file from `Request.Files` and then save it. (Including the various things you need to do to get the right file name and path.) The innovation this time is that the user might be uploading multiple files and you don't know many. To find out, you can get `Request.Files.Count`.

With this number in hand, you can loop through `Request.Files`, fetch each file in turn, and save it. When you want to loop a known number of times through a collection, you can use a `for` loop, like this:

```
for(int i =0; i < numFiles; i++) {
    var uploadedFile = Request.Files[i];
    if (uploadedFile.ContentLength > 0) {
        fileName = Path.GetFileName(uploadedFile.FileName);

    // etc.
}
```

The variable `i` is just a temporary counter that will go from zero to whatever upper limit you set. In this case, the upper limit is the number of files. But because the counter starts at zero, as is typical for counting scenarios in ASP.NET, the upper limit is actually one less than the file count. (If three files are uploaded, the count is zero to 2.)

The `uploadedCount` variable totals all the files that are successfully uploaded and saved. This code accounts for the possibility that an expected file may not be able to be uploaded.

4. Run the page in a browser. The browser displays the page and its two upload boxes.
5. Select two files to upload.
6. Click **Add another file**. The page displays a new upload box.

7. Click **Upload**.
8. In the website, right-click the project folder and then click **Refresh**.
9. Open the *UploadedFiles* folder to see the successfully uploaded files.

Introduction to Debugging ASP.NET Web Pages (Razor) Sites

2/20/2020 • 9 minutes to read • Edit Online

by Tom FitzMacken

This article explains various ways to debug pages in an ASP.NET Web Pages (Razor) website. Debugging is the process of finding and fixing errors in your code pages.

What you'll learn:

- How to display information that helps analyze and debug pages.
- How to use debugging tools in Visual Studio.

These are the ASP.NET features introduced in the article:

- The `ServerInfo` helper.
- `ObjectInfo` helper.

Software versions

- ASP.NET Web Pages (Razor) 3
- Visual Studio 2013

This tutorial also works with ASP.NET Web Pages 2. You can use WebMatrix 3 but the integrated debugger is not supported.

An important aspect of troubleshooting errors and problems in your code is to avoid them in the first place. You can do that by putting sections of your code that are likely to cause errors into `try/catch` blocks. For more information, see the section on handling errors in Introduction to ASP.NET Web Programming Using the Razor Syntax.

The `ServerInfo` helper is a diagnostic tool that gives you an overview of information about the web server environment that hosts your page. It also shows you HTTP request information that's sent when a browser requests the page. The `ServerInfo` helper displays the current user identity, the type of browser that made the request, and so on. This kind of information can help you troubleshoot common issues.

1. Create a new web page named *ServerInfo.cshtml*.
2. At the end of the page, just before the closing `</body>` tag, add `@ServerInfo.GetHtml()`:

```
<!DOCTYPE html>
<html>
    <head>
        <title></title>
    </head>
    <body>
   @ServerInfo.GetHtml()
    </body>
</html>
```

You can add the `ServerInfo` code anywhere in the page. But adding it at the end will keep its output

separate from your other page content, which makes it easier to read.

> **NOTE**
>
> **Important** You should remove any diagnostic code from your web pages before you move web pages to a production server. This applies to the `ServerInfo` helper as well as the other diagnostic techniques in this article that involve adding code to a page. You don't want your website visitors to see information about your server name, user names, paths on your server, and similar details, because this type of information might be useful to people with malicious intent.

3. Save the page and run it in a browser.

The `ServerInfo` helper displays four tables of information in the page:

- Server Configuration. This section provides information about the hosting web server, including computer name, the version of ASP.NET you're running, the domain name, and server time.
- ASP.NET Server Variables. This section provides details about the many HTTP protocol details (called HTTP variables) and values that are part of each web page request.
- HTTP Runtime Information. This section provides details about that the version of the Microsoft .NET Framework that your web page is running under, the path, details about the cache, and so on. (As you learned in Introduction to ASP.NET Web Programming Using the Razor Syntax, ASP.NET Web Pages using the Razor syntax are built on Microsoft's ASP.NET web server technology, which is itself built on an extensive software development library called the .NET Framework.)
- Environment Variables. This section provides a list of all the local environment variables and their values on the web server.

  A full description of all the server and request information is beyond the scope of this article, but you can see that the `ServerInfo` helper returns a lot of diagnostic information. For more information about the values that `ServerInfo` returns, see Recognized Environment Variables on the Microsoft TechNet website and IIS Server Variables on the MSDN website.

Embedding Output Expressions to Display Page Values

Another way to see what's happening in your code is to embed output expressions in the page. As you know, you can directly output the value of a variable by adding something like `@myVariable` or `@(subTotal * 12)` to the page. For debugging, you can place these output expressions at strategic points in your code. This enables you to see the value of key variables or the result of calculations when your page runs. When you're done debugging, you can remove the expressions or comment them out. This procedure illustrates a typical way to use embedded expressions to help debug a page.

1. Create a new WebMatrix page that's named *OutputExpression.cshtml*.
2. Replace the page content with the following:

```
<!DOCTYPE html>
<html>
    <head>
        <title></title>
    </head>
    <body>

    @{
        var weekday = DateTime.Now.DayOfWeek;
        // As a test, add 1 day to the current weekday.
        if(weekday.ToString() != "Saturday") {
            // If weekday is not Saturday, simply add one day.
            weekday = weekday + 1;
        }
        else {
            // If weekday is Saturday, reset the day to 0, or Sunday.
            weekday = 0;
        }
        // Convert weekday to a string value for the switch statement.
        var weekdayText = weekday.ToString();

        var greeting = "";

        switch(weekdayText)
        {
            case "Monday":
                greeting = "Ok, it's a marvelous Monday.";
                break;
            case "Tuesday":
                greeting = "It's a tremendous Tuesday.";
                break;
            case "Wednesday":
                greeting = "Wild Wednesday is here!";
                break;
            case "Thursday":
                greeting = "All right, it's thrifty Thursday.";
                break;
            case "Friday":
                greeting = "It's finally Friday!";
                break;
            case "Saturday":
                greeting = "Another slow Saturday is here.";
                break;
            case "Sunday":
                greeting = "The best day of all: serene Sunday.";
                break;
            default:
                break;
        }
    }

    <h2>@greeting</h2>

    </body>
</html>
```

The example uses a `switch` statement to check the value of the `weekday` variable and then display a different output message depending on which day of the week it is. In the example, the `if` block within the first code block arbitrarily changes the day of the week by adding one day to the current weekday value. This is an error introduced for illustration purposes.

3. Save the page and run it in a browser.

   The page displays the message for the wrong day of the week. Whatever day of the week it actually is, you'll see the message for one day later. Although in this case you know why the message is off (because the code

deliberately sets the incorrect day value), in reality it's often hard to know where things are going wrong in the code. To debug, you need to find out what's happening to the value of key objects and variables such as `weekday`.

4. Add output expressions by inserting `@weekday` as shown in the two places indicated by comments in the code. These output expressions will display the values of the variable at that point in the code execution.

```
var weekday = DateTime.Now.DayOfWeek;
// DEBUG: Display the initial value of weekday.
@weekday

// As a test, add 1 day to the current weekday.
if(weekday.ToString() != "Saturday") {
    // If weekday is not Saturday, simply add one day.
    weekday = weekday + 1;
}
else {
    // If weekday is Saturday, reset the day to 0, or Sunday.
    weekday = 0;
}

// DEBUG: Display the updated test value of weekday.
@weekday

// Convert weekday to a string value for the switch statement.
var weekdayText = weekday.ToString();
```

5. Save and run the page in a browser.

   The page displays the real day of the week first, then the updated day of the week that results from adding one day, and then the resulting message from the `switch` statement. The output from the two variable expressions (`@weekday`) has no spaces between the days because you didn't add any HTML `<p>` tags to the output; the expressions are just for testing.

   Now you can see where the error is. When you first display the `weekday` variable in the code, it shows the correct day. When you display it the second time, after the `if` block in the code, the day is off by one. So you know that something has happened between the first and second appearance of the weekday variable. If this were a real bug, this kind of approach would help you narrow down the location of the code that's causing the problem.

6. Fix the code in the page by removing the two output expressions you added, and removing the code that changes the day of the week. The remaining, complete block of code looks like the following example:

```
@{
    var weekday = DateTime.Now.DayOfWeek;
    var weekdayText = weekday.ToString();

    var greeting = "";

    switch(weekdayText)
    {
        case "Monday":
            greeting = "Ok, it's a marvelous Monday.";
            break;
        case "Tuesday":
            greeting = "It's a tremendous Tuesday.";
            break;
        case "Wednesday":
            greeting = "Wild Wednesday is here!";
            break;
        case "Thursday":
            greeting = "All right, it's thrifty Thursday.";
            break;
        case "Friday":
            greeting = "It's finally Friday!";
            break;
        case "Saturday":
            greeting = "Another slow Saturday is here.";
            break;
        case "Sunday":
            greeting = "The best day of all: serene Sunday.";
            break;
        default:
            break;
    }
}
```

7. Run the page in a browser. This time you see the correct message displayed for the actual day of the week.

Using the ObjectInfo Helper to Display Object Values

The `ObjectInfo` helper displays the type and the value of each object you pass to it. You can use it to view the value of variables and objects in your code (like you did with output expressions in the previous example), plus you can see data type information about the object.

1. Open the file named *OutputExpression.cshtml* that you created earlier.

2. Replace all code in the page with the following block of code:

```
<!DOCTYPE html>
<html>
    <head>
        <title></title>
    </head>
    <body>
    @{
      var weekday = DateTime.Now.DayOfWeek;
      @ObjectInfo.Print(weekday)
      var weekdayText = weekday.ToString();

      var greeting = "";

      switch(weekdayText)
      {
          case "Monday":
              greeting = "Ok, it's a marvelous Monday.";
              break;
          case "Tuesday":
              greeting = "It's a tremendous Tuesday.";
              break;
          case "Wednesday":
              greeting = "Wild Wednesday is here!";
              break;
          case "Thursday":
              greeting = "All right, it's thrifty Thursday.";
              break;
          case "Friday":
              greeting = "It's finally Friday!";
              break;
           case "Saturday":
              greeting = "Another slow Saturday is here.";
              break;
           case "Sunday":
              greeting = "The best day of all: serene Sunday.";
              break;
          default:
              break;
      }
    }
    @ObjectInfo.Print(greeting)
    <h2>@greeting</h2>

    </body>
</html>
```

3. Save and run the page in a browser.

In this example, the `ObjectInfo` helper displays two items:

- The type. For the first variable, the type is `DayOfWeek`. For the second variable, the type is `String`.
- The value. In this case, because you already display the value of the greeting variable in the page, the value is displayed again when you pass the variable to `ObjectInfo`.

For more complex objects, the `ObjectInfo` helper can display more information — basically, it can display the types and values of all of an object's properties.

Using Debugging Tools in Visual Studio

For a more comprehensive debugging experience, use Visual Studio. With Visual Studio, you can set a breakpoint in your code at the line that you want to inspect.

```
@{
    Layout = "~/_SiteLayout.cshtml";
    Page.Title = "Home Page";
    var myTime = DateTime.Now.TimeOfDay;
}
```

When you test the web site, the executing code halts at the breakpoint.

```
@{
    Layout = "~/_SiteLayout.cshtml";
    Page.Title = "Home Page";
    var myTime = DateTime.Now.TimeOfDay;
}
```

You can examine the current values of the variables, and step through the code line-by-line.

```
@{
    Layout = "~/_SiteLayout.cshtml";
    Page.Title = "Home Page";
    var myTime = DateTime.Now.TimeOfDay;
}
    myTime {14:54:10.4713083}
```

For information about using the integrated debugger in Visual Studio to debug ASP.NET Razor pages, see Programming ASP.NET Web Pages (Razor) Using Visual Studio.

ASP.NET Web Pages (Razor) Troubleshooting Guide

2/20/2020 • 7 minutes to read • Edit Online

by Tom FitzMacken

This article describes issues that you might have when working with ASP.NET Web Pages (Razor) and some suggested solutions.

Software versions

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2 and ASP.NET Web Pages 1.0.

This topic contains the following sections:

- Issues with Running Pages
- Issues with Razor Code
- Issues with Security and Membership
- Issues with Sending Email
- Additional Resources

For general questions, see ASP.NET Web Pages (Razor) FAQ.

Issues with Running Pages

A variety of issues can prevent *.cshtml* and *.vbhtml* pages from running properly. This section lists common error messages and likely causes.

HTTP Error 403 - Forbidden: Access is denied

You do not have permission to view this directory or page using the credentials that you supplied.

This error can occur if the server is not running the correct version of the .NET Framework. Make sure that the computer that's running the server (locally or remotely) has at least the .NET Framework 4 installed. Also make sure that the application itself is configured to run the right version.

If you see this problem locally while working in WebMatrix, click the **Site** workspace, and then in the treeview click **Settings**. In the **Select .NET Framework Version** list, select **.NET 4 (Integrated)**. If this version is already set, try running WebMatrix as an administrator.

Make sure that the root of your website has at least one *.cshtml* file in it.

If you see this error when the web server is on a remote server, contact the server administrator. Make sure that the server has the .NET Framework 4 or later installed. Also make sure that the application is running in an application pool that's configured to use that version of the.NET Framework.

If you have control over the server, make sure it's running the correct version of the .NET Framework. You might also try repairing the installation by running the `aspnet_regiis -iru` command. (For example, if you install IIS after you install the .NET Framework, IIS will not be correctly configured to run ASP.NET pages.) For more information, see ASP.NET IIS Registration Tool (Aspnet_regiis.exe).

HTTP Error 403.14 - Forbidden

The Web server is configured to not list the contents of this directory.

This error can occur if you request a resource that's protected (like the *Web.config* file) or that's in a folder that's protected (like *App_Data* or *App_Code*).

HTTP Error 404.17 - Not Found

The requested content appears to be script and will not be served by the static file handler.

This error can occur if the server is not configured correctly to use the .NET Framework 4 or later, and therefore does not recognize the code in `@{ }` blocks. See the description earlier for *HTTP Error 403 - Forbidden: Access is denied*.

HTTP Error 404.7 - Not Found

The request filtering module is configured to deny the file extension

This error can occur if *.cshtml* or *.vbhtml* extensions have been explicitly blocked on the server. A symptom of this problem is that URLs work when they do not include the extension, but URLs that include *.cshtml* or *.vbhtml* do not work. A possible solution is to re-enable the extensions in the site's *Web.config* file. The following example shows how to enable the *.cshtml* extension.

```
<system.webServer>
  <security>
   <requestFiltering>
     <fileExtensions>
       <remove fileExtension=".cshtml" />
       <add fileExtension=".cshtml" allowed="true" />
     </fileExtensions>
    </requestFiltering>
  </security>
</system.webServer>
```

HTTP Error 404.8 - Not Found

The request filtering module is configured to deny a path in the URL that contains a hiddenSegment section.

This error can occur if you request a resource that's protected (like the *Web.config* file) or that's in a folder that's protected (like *App_Data* or *App_Code*).

This type of page is not served (Server Error in '/' Application)

See the description earlier for HTTP Error 404.17.

Issues with Razor code

The name '*class*' does not exist in the current context

Often, a reason you see this error is that `class` references a helper, but the helper is not installed. For example, if you try to use a helper, but if you haven't installed the package from NuGet, you'll see this error. Use the Gallery in WebMatrix to find and install the helper.

If the helper is installed, but the page still doesn't recognize it, try adding add a `using` statement to the code. In the `using` statement, reference the namespace that includes the helper. For example, the basic helpers that are in the ASP.NET Web Helpers package are in the `System.Web.Helpers` namespace. At the top of the page where you want to use the helper, add this line:

```
@using Microsoft.Web.Helpers;
```

Issues with Security and Membership

If you are using the built-in security (membership) system in ASP.NET Web Pages (Razor), you might encounter the

following issues.

To call this method, the "Membership.Provider" property must be an instance of "ExtendedMembershipProvider"

This error can indicate that no `AspNetSqlMembershipProvider` class is configured. (A symptom is that the site works fine locally but throws this error when you publish it to a hosting provider's server.) One fix for this problem is to explicitly enable simple membership by adding the following to the site's *Web.config* file:

```
<configuration>

  <!-- other setting -->

  <appSettings>
    <add key="enableSimpleMembership" value="true" />
  </appSettings>

  <!-- other settings -->

</configuration>
```

Issues with Sending Email

Problems with sending email can be challenging to debug. An initial problem can be that you can't connect to the SMTP server. If the connection is successful, ASP.NET hands the message off to the SMTP server. However, there can be problems with the message itself that prevents the SMTP server from sending it.

If your application does not successfully send email, try the following:

- The SMTP server name is often something like `smtp.provider.com` or `smtp.provider.net`. However, if you publish your site to a hosting provider, the SMTP server name at that point might be `localhost`. This situation occurs because after you've published and your site is running on the provider's server, the SMTP server might be local from the perspective of your application. This change in server names might mean that you have to change the SMTP server name as part of your publishing process.
- The port number is usually 25. However, some providers require you to use port 587 or some other port. Check with the owner of the SMTP server what port number they expect you to use.
- Make sure that you use the right credentials. If you've published your site to a hosting provider, use the credentials that the provider has specifically indicated are for email. These credentials might be different from the credentials you use to publish.
- Sometimes you don't need credentials at all. If you're sending email by using your personal ISP, your email provider might already know your credentials. After you publish, you might need to use different credentials than when you test on your local computer.
- If your email provider uses encryption, set `WebMail.EnableSsl` to `true`.

If there is an error sending email, you might see a standard ASP.NET error message, which looks like this:

Server Error in '/' Application.

The specified string is not in the form required for an e-mail address.

Description: An unhandled exception occurred during the execution of the current web request. Please review the stack trace for more code.

Exception Details: System.FormatException: The specified string is not in the form required for an e-mail address.

Source Error:

```
Line 16:
Line 17:        // Send email
Line 18:        WebMail.Send(to: customerEmail,
Line 19:            subject: "Help request from - " + customerName,
Line 20:            body: customerRequest
```

You can also debug problems with sending email by using a `try-catch` block, as in the following example. When you use a `try-catch` block, ASP.NET does not display its standard error messages. Instead, you can capture the error in the `catch` portion of the block.

```
var errorMessage = "";
try {
    // Initialize WebMail helper
    WebMail.SmtpServer = "your-SMTP-server-name";
    WebMail.SmtpPort = 25;   // Or the port you've been told to use
    WebMail.EnableSsl = false;
    WebMail.UserName = "your-login-name";
    WebMail.Password = "your-password";
    WebMail.From = "your-from-address";

    WebMail.Send(to: test-To-address,
        subject: "Test email message",
        body: "This is a debug email message"
    );
}
catch (Exception ex ) {
errorMessage = ex.Message;
}

// Other code or markup here ...

<!-- In markup, add the following -->
@if(!errorMessage.IsEmpty()){
    <p>@errorMessage</p>
}
```

Substitute the appropriate values for `your-SMTP-server-name`, and so on. Some of the error messages you might see this way include the following:

- *Failure sending mail.*

  -or-

  A connection attempt failed because the connected party did not properly respond after a period of time, or established connection failed because connected host has failed to respond

  This error usually means that the application could not connect to the SMTP server. Check the server name and port number.

- *Mailbox unavailable. The server response was: 5.1.0 <someuser@invaliddomain> sender rejected : invalid sender domain*

  This message can indicate that the `From` address is not correct or is missing.

- *The specified string is not in the form required for an email address.*

This error might indicate that the value of the `To` or `From` properties are not recognized as email addresses. (ASP.NET cannot check that the email address is valid, only that it's in the correct format, like *name@domain.com*.)

> **NOTE**
>
> Remove the markup that displays the error (`@errorMessage`) before you publish the page to a live site. It's not a good idea to let users see error messages that you get from a server.

Adding Security and Membership to an ASP.NET Web Pages (Razor) Site

2/20/2020 • 15 minutes to read • Edit Online

by Tom FitzMacken

This article explains how to secure an ASP.NET Web Pages (Razor) website so that some of the pages are available only to people who log in. (You'll also see how to create pages that anyone can access.)

What you'll learn:

- How to create a website that has a registration page and a login page so that for some pages you can limit access to only members.
- How to create public and member-only pages.
- How to define roles, which are groups that have different security permissions on your site, and how to assign users to a role.
- How to use CAPTCHA to prevent automated programs (bots) from creating member accounts.

These are the ASP.NET features introduced in the article:

- The WebMatrix **Starter Site** template.
- The `WebSecurity` helper and `Roles` class.
- The `ReCaptcha` helper.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- WebMatrix 3
- ASP.NET Web Helpers Library

You can set up your website so that users can log into it — that is, so that the site supports *membership*. This can be useful for many reasons. For example, your site might have pages that should be available only to members. In some cases, you might require users to log in in order to send you feedback or leave a comment.

Even if your website supports membership, users aren't necessarily required to log in before they use some of the pages on the site. Users who aren't logged in are known as *anonymous users*.

A user can register on your website and can then log in to the site. The website requires a user name (an email address) and a password to confirm that users are who they claim to be. This process of logging in and confirming a user's identity is known as *authentication*.

You can set up security and membership in different ways:

- If you're using WebMatrix, an easy way is to create as new site based on the **Starter Site** template. This template is already configured for security and membership and already has a registration page, a login page, and so on.

  The site created by the template also has an option to let users log in using an external site like Facebook, Google, or Twitter.

- If you want to add security to an existing site, or if you don't want to use the **Starter Site** template, you can

create your own registration page, login page, and so on.

This article focuses on the first option — how to add security by using the **Starter Site** template. It also provides some basic information about how to implement your own security and then provides links to more information about how to do that. There is also information about how to enable external logins, which is described in more detail in a separate article.

Creating Website Security Using the Starter Site Template

In WebMatrix, you can use the **Starter Site** template to create a website that contains the following:

- A database that's used to store user names and passwords for your members.
- A registration page where anonymous (new) users can register.
- A login and logout page.
- A password recovery and reset page.

The following procedure describes how to create the site and configure it.

1. Start WebMatrix and in the **Quick Start** page, select **Site From Template**.

2. Select the **Starter Site** template and then click **OK**. WebMatrix creates a new site.

3. In the left pane, click the **Files** workspace selector.

4. In the root folder of your website, open the *_AppStart.cshtml* file, which is a special file that's used to contain global settings. It contains some statements that are commented out using the `//` characters:

   ```
   //WebMail.SmtpServer = "mailserver.example.com";
   //WebMail.EnableSsl = true;
   //WebMail.UserName = "username@example.com";
   //WebMail.Password = "your-password";
   //WebMail.From = "your-name-here@example.com";
   ```

   These statements configure the `WebMail` helper, which can be used to send email. The membership system can use email to send confirmation messages when users register or when they want to change their passwords. (For example, after users register, they get an email that includes a link that they can click in order to finish the registration process.)

   Sending email requires access to an SMTP server, as described in Adding Email to an ASP.NET Web Pages Site. You'll store the email settings in this central *_AppStart.cshtml* file so that you don't have to code them repeatedly into each page that can send email. (You don't need to configure SMTP settings to set up a registration database; you only need SMTP settings if you want to validate users from their email alias and let users reset a forgotten password.)

5. Uncomment the statements by removing `//` from in front of each one.

   If you do not want to set up email confirmation, you can skip this step and the next step. If the SMTP values are not set, the new account is immediately available without a confirmation email.

6. Modify the following email-related settings in the code:

   - Set `WebMail.SmtpServer` to the name of the SMTP server that you have access to.

   - Leave `WebMail.EnableSsl` set to `true`. This setting secures the credentials that are sent to the SMTP server by encrypting them.

   - Set `WebMail.UserName` to the user name for your SMTP server account.

- Set `WebMail.Password` to the password for your SMTP server account.
- Set `WebMail.From` to your own email address. This is the email address that the message is sent from.

> **NOTE**
>
> **Tip** For additional information about the values for these properties, see Configuring Email Settings in Customizing Site-Wide Behavior for ASP.NET Web Pages.

7. Save and close *_AppStart.cshtml*.
8. Run the *Default.cshtml* page in a browser.

> **NOTE**
>
> If you see an error that tells you that a property must be an instance of `ExtendedMembershipProvider`, the site might not be configured to use the ASP.NET Web Pages membership system (SimpleMembership). This can sometimes occur if a hosting provider's server is configured differently than your local server. To fix this, add the following element to the site's *Web.config* file:
>
> ```
> <appSettings>
>  <add key="enableSimpleMembership" value="true" />
> </appSettings>
> ```
>
> Add this element as a child of the `<configuration>` element and as a peer of the `<system.web>` element.

9. In the upper-right corner of the page, click the **Register** link. The *Register.cshtml* page is displayed.
10. Enter a user name and password and then click **Register**.

When you created the website from the **Starter Site** template, a database named *StarterSite.sdf* was created in the site's *App_Data* folder. During registration, your user information is added to the database. If you set the SMTP values, a message is sent to the email address you used so you can finish registering.

11. Go to your email program and find the message, which will have your confirmation code and a hyperlink to the site.

12. Click the hyperlink to activate your account. The confirmation hyperlink opens a registration confirmation page.

13. Click the **Login** link, and then log in using the account that you registered.

    After you log in, the **Login** and **Register** links are replaced by a **Logout** link. Your login name is displayed as a link. (The link lets you go to a page where you can change your password.)

> **NOTE**
> By default, ASP.NET web pages send credentials to the server in clear text (as human-readable text). A production site should use secure HTTP (https://, also known as the *secure sockets layer* or SSL) to encrypt sensitive information that's exchanged with the server. You can required email messages to be sent using SSL by setting `WebMail.EnableSsl=true` as in the previous example. For more information about SSL, see Securing Web Communications: Certificates, SSL, and https://.

Additional Membership Functionality in the Site

Your site contains other functionality that lets users manage their accounts. Users can do the following:

- Change their passwords. After logging in, they can click the user name (which is a link). This takes them to a page where they can create a new password (*Account/ChangePassword.cshtml*).
- Recover a forgotten password. On the login page, there's a link (**Did you forget your password?**) that takes users to a page (*Account/ForgotPassword.cshtml*) where they can enter an email address. The site sends them an email message that has a link that they can click in order to set a new password (*Account/PasswordReset.cshtml*).

You can also let users can also log in using an external site, as explained later.

Creating a Members-Only Page

For the time being, anyone can browse to any page in your website. But you might want to have pages that are available only to people who have logged in (that is, to members). ASP.NET lets you create pages that can be accessed only by logged-in members. Typically, if anonymous users try to access a members-only page, you redirect them to the login page.

In this procedure, you'll create a folder that will contain pages that are available only to logged-in users.

1. At the root of the site, create a new folder. (In the ribbon, click the arrow underneath **New** and then choose **New Folder**.)

2. Name the new folder *Members*.

3. Inside the *Members* folder, create a new page and named it *MembersInformation.cshtml*.

4. Replace the existing content with the following code and markup:

```
@{
    if (!WebSecurity.IsAuthenticated) {
        Response.Redirect("~/Account/Login?returnUrl="
            + Request.Url.LocalPath);
    }
    Layout = "~/_SiteLayout.cshtml";
    Page.Title = "Members Information";
}
<!DOCTYPE html>
<html lang="en">
  <head>
    <meta charset="utf-8" />
    <title>Members Information</title>
  </head>
  <body>
    <p>You can only see this information if you've logged into the site.</p>
  </body>
</html>
```

This code tests the `IsAuthenticated` property of the `WebSecurity` object, which returns `true` if the user has logged in. If the user is not logged in, the code calls `Response.Redirect` to send the user to the *Login.cshtml* page in the *Account* folder.

The URL of the redirection includes a `returnUrl` query string value that uses `Request.Url.LocalPath` to set the path of the current page. If you set the `returnUrl` value in the query string like this (and if the return URL is a local path), the login page will return users to this page after they log in.

The code also sets *_SiteLayout.cshtml* page as its layout page. (For more about layout pages, see Creating a Consistent Layout in ASP.NET Web Pages Sites.)

5. Run the site. If you're still logged in, click the **Logout** button at the top of the page.

6. In the browser, request the page */Members/MembersInformation*. For example, the URL might look like this:

   ```
   http://localhost:38366/Members/MembersInformation
   ```

   (The port number (38366) will probably be different in your URL.)

   You're redirected to the *Login.cshtml* page, because you aren't logged in.

7. Log in using the account you created earlier. You're redirected back to the *MembersInformation* page. Because you're logged in, this time you see the page contents.

To secure access to multiple pages, you can do this:

- Add the security check to each page.
- Create a *_PageStart.cshtml* page in the folder where you keep protected pages, and add the security check there. The *_PageStart.cshtml* page acts as a kind of global page for all the pages in the folder. This technique is explained in more detail in Customizing Site-Wide Behavior for ASP.NET Web Pages.

Creating Security for Groups of Users (Roles)

If your site has a lot of members, it's not efficient to check permission for each user individually before you let them see a page. What you can do instead is to create groups, or *roles*, that individual members belong to. You can then check permissions based on role. In this section, you'll create an "admin" role and then create a page that's accessible to users who are in (who belong to) that role.

The ASP.NET membership system is set up to support roles. However, unlike membership registration and login, the **Starter Site** template does not contain pages that help you manage roles. (Managing roles is an administrative task rather than a user task.) However, you can add groups directly in the membership database in WebMatrix.

1. In WebMatrix, click the **Databases** workspace selector.

2. In the left pane, open the *StarterSite.sdf* node, open the **Tables** node, and then double-click the *webpages_Roles* table.

3. Add a role named "admin". The *RoleId* field is filled in automatically. (It's the primary key and has been set

to be an identify field, as explained in Introduction to Working with a Database in ASP.NET Web Pages Sites.)

4. Take note of what the value is for the *RoleId* field. (If this is the first role you're defining, it will be 1.)

Table - (StarterSi...df).webpages_Roles

RoleId	RoleName
1	admin

5. Close the *webpages_Roles* table.

6. Open the *UserProfile* table.

7. Make a note of the *UserId* value of one or more of the users in the table and then close the table.

8. Open the *webpages_UserInRoles* table and enter a *UserID* and a *RoleID* value into the table. For example, to put user 2 into the "admin" role, you'd enter these values:

Table - (StarterSi...pages_UsersInRoles

UserId	RoleId
2	1

9. Close the *webpages_UsersInRoles* table.

   Now that you have roles defined, you can configure a page that's accessible to users who are in that role.

10. In the website root folder, create a new page named *AdminError.cshtml* and replace the existing content with the following code. This will be the page that users are redirected to if they aren't allowed access to a page.

```
@{
    Layout = "~/_SiteLayout.cshtml";
    PageData["Title"] = "Admin-only Error";
}
<p>You must log in as an admin to access that page.</p>
```

11. In the website root folder, create a new page named *AdminOnly.cshtml* and replace the existing code with the following code:

```
@{
    Layout = "~/_SiteLayout.cshtml";
    PageData["Title"] = "Administrators only";
}

@if ( Roles.IsUserInRole("admin")) {
    <span> Welcome <b>@WebSecurity.CurrentUserName</b>! </span>
}
else {
     Response.Redirect("~/AdminError");
}
```

    The `Roles.IsUserInRole` method returns `true` if the current user is a member of the specified role (in this case, the "admin" role).

12. Run *Default.cshtml* in a browser, but don't log in. (If you're already logged in, log out.)

13. In the browser's address bar, add *AdminOnly* in the URL. (In other words, request the *AdminOnly.cshtml* file.) You're redirected to the *AdminError.cshtml* page, because you aren't currently logged in as a user in the "admin" role.

14. Return to *Default.cshtml* and log in as the user you added to the "admin" role.
15. Browse to *AdminOnly.cshtml* page. This time you see the page.

Preventing Automated Programs from Joining Your Website

The login page will not stop automated programs (sometimes referred to as *web robots* or *bots*) from registering with your website. This procedure describes how to enable a ReCaptcha test for the registration page.

1. Register your website at ReCaptcha.Net (http://recaptcha.net). When you've completed registration, you'll get a public key and a private key.
2. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already.
3. In the *Account* folder, open the file named *Register.cshtml*.
4. In the code at the top of the page, find the following lines and uncomment them by removing the `//` comment characters:

```
if (!ReCaptcha.Validate("PRIVATE_KEY")) {
    ModelState.AddError("recaptcha", "Captcha response was not correct");
}
```

5. Replace `PRIVATE_KEY` with your own ReCaptcha private key.
6. In the markup of the page, remove the `@*` and `*@` commenting characters from around the following lines in the page markup:

```
@ReCaptcha.GetHtml("PUBLIC_KEY", theme: "white")
@Html.ValidationMessage("recaptcha")
```

7. Replace `PUBLIC_KEY` with your key.
8. If you haven't removed it already, remove the `<div>` element that contains text that starts with "To enable CAPTCHA verification ...". (Remove the entire `<div>` element and its contents.)
9. Run *Default.cshtml* in a browser. If you're logged into the site, click the **Logout** link.
10. Click the **Register** link and test the registration using the CAPTCHA test.

For more information about the `ReCaptcha` helper, see Using a CATPCHA to Prevent Automated Programs (Bots) from Using Your ASP.NET Web Site.

Letting Users Log In Using an External Site

The **Starter Site** template includes code and markup that lets users log in using Facebook, Windows Live, Twitter, Google, or Yahoo. By default, this functionality is not enabled. The general procedure for using letting users log in using these external providers is this:

- Decide which of the external sites you want to support.
- If required, go to that site and set up a login app. (For example, you have to do this in order to allow Facebook logins.)
- In your site, configure the provider. In most cases, you just have to uncomment some code in the *_AppStart.cshtml* file.
- Add markup to the registration page that lets people link to the external site for logging in. You can usually copy the markup you need and change the text slightly.

You can find step-by-step instructions in the topic Enabling Login from External Sites in an ASP.NET Web Pages Site.

After a user logs in from another site, the user returns to your site and *associates* that login with your site. In effect, this creates a membership entry in your site for the user's external login. This lets you use the normal facilities of membership (such as roles) with the external login.

Adding Security to an Existing Website

The procedure earlier in this article relies on using the **Starter Site** template as the basis for website security. If it isn't practical for you to start from the **Starter Site** template or to copy the relevant pages from a site based on that template, you can implement the same type of security in your own site by coding it yourself. You create the same types of pages — registration, login, and so on — and then use helpers and classes to set up membership.

The basic process is described in the blog post THE most basic way to implement ASP.NET Razor security. Most of the work is done using the following methods and properties of the `WebSecurity` helper:

- WebSecurty.UserExists, WebSecurity.CreateUserAndAccount. These methods let you determine whether someone is already registered and to register them.
- WebSecurty.IsAuthenticated. This property lets you determine whether the current user is logged in. This is useful to redirect users to a login page if they have not already logged in.
- WebSecurity.Login, WebSecurity.Logout. These methods log a user in or out.

- WebSecurity.CurrentUserName. This property is useful for displaying the current user's logged-in name (if the user is logged in).
- WebSecurity.ConfirmAccount. This method is useful if you set up email confirmation for registration. (Details are described in the blog post Using the confirmation feature for ASP.NET Web Pages security.)

To manage roles, you can use the Roles and Membership classes, as described in the blog entry.

Logging In Using External Sites in an ASP.NET Web Pages (Razor) Site

2/20/2020 • 7 minutes to read • Edit Online

by Tom FitzMacken

This article explains how to log in to your ASP.NET Web Pages (Razor) site using Facebook, Google, Twitter, Yahoo, and other sites — that is, how to support OAuth and OpenID in your site.

What you'll learn:

- How to enable login from other sites when you use the WebMatrix Starter Site template.

This is the ASP.NET feature introduced in the article:

- The `OAuthWebSecurity` helper.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- WebMatrix 3

ASP.NET Web Pages includes support for OAuth and OpenID providers. Using these providers, you can let users log into your site using their existing credentials from Facebook, Twitter, Microsoft, and Google. For example, to log in using a Facebook account, users can just choose a Facebook icon, which redirects them to the Facebook login page where they enter their user information. They can then associate the Facebook login with their account on your site. A related enhancement to the Web Pages membership features is that users can associate multiple logins (including logins from social networking sites) with a single account on your website.

This image shows the Login page from the **Starter Site** template, where a user can choose a Facebook, Twitter, Google or Microsoft icon to enable logging in with an external account:

You can enable OAuth and OpenID membership by uncommenting a few lines of code in the **Starter Site** template. The methods and properties you use to work with the OAuth and OpenID providers are in the

`WebMatrix.Security.OAuthWebSecurity` class. The **Starter Site** template includes a full membership infrastructure, complete with a login page, a membership database, and all the code you need to let users log into your site using either local credentials or those from another site.

This section provides an example of how to let users log in from external sites to a site that's based on the **Starter Site** template. After creating a starter site, you do this (details follow):

- For the sites that use an OAuth provider (Facebook, Twitter, and Microsoft), you create an application on the external site. This gives you application keys that you'll need in order to invoke the login feature for those sites.
- For sites that use an OpenID provider (Google), you do not have to create an application. For all of these sites, you must have an account in order to log in and to create developer applications.

> **NOTE**
> Microsoft applications only accept a live URL for a working website, so you cannot use a local website URL for testing logins.

- Edit a few files in your website in order to specify the appropriate authentication provider and to submit a login to the site you want to use.

This article provides separate instructions for the following tasks:

- Enabling Google logins
- Enabling Facebook logins
- Enabling Twitter logins

Enabling Google Logins

1. Create or open an ASP.NET Web Pages site that's based on the WebMatrix Starter Site template.
2. Open the *_AppStart.cshtml* page and uncomment the following line of code.

```
OAuthWebSecurity.RegisterGoogleClient();
```

Testing Google login

1. Run the *default.cshtml* page of your site and choose the **Log in** button.
2. On the *Login* page, in the **Use another service to log in** section, choose either the **Google** or **Yahoo** submit button. This example uses the Google login.

   The web page redirects the request to the Google login page.

3. Enter credentials for an existing Google account.

4. If Google asks you whether you want to allow *Localhost* to use information from the account, click **Allow**.

   The code uses the Google token to authenticate the user, and then returns to this page on your website. This page lets users associate their Google login with an existing account on your website, or they can register a new account on your site to associate the external login with.

5. Choose the **Associate** button. The browser returns to your application's home page.

Enabling Facebook Logins

1. Go to the Facebook developers site (log in if you're not already logged in).

2. Choose the **Create New App** button, and then follow the prompts to name and create the new application.

3. In the section **Select how your app will integrate with Facebook**, choose the **Website** section.

4. Fill in the **Site URL** field with the URL of your site (for example, `http://www.example.com`). The **Domain** field is optional; you can use this to provide authentication for an entire domain (such as *example.com*).

> **NOTE**
> If you are running a site on your local computer with a URL like `http://localhost:12345` (where the number is a local port number), you can add this value to the **Site URL** field for testing your site. However, any time the port number of your local site changes, you will need to update the **Site URL** field of your application.

5. Choose the **Save Changes** button.
6. Choose the **Apps** tab again, and then view the start page for your application.
7. Copy the **App ID** and **App Secret** values for your application and paste them into a temporary text file. You will pass these values to the Facebook provider in your website code.
8. Exit the Facebook developer site.

Now you make changes to two pages in your website so that users will able to log into the site using their Facebook accounts.

1. Create or open an ASP.NET Web Pages site that's based on the WebMatrix Starter Site template.
2. Open the *_AppStart.cshtml* page and uncomment the code for the Facebook OAuth provider. The uncommented code block looks like the following:

```
OAuthWebSecurity.RegisterFacebookClient(
        appId: "",
        appSecret: "");
```

3. Copy the **App ID** value from the Facebook application as the value of the `appId` parameter (inside the quotation marks).
4. Copy **App Secret** value from the Facebook application as the `appSecret` parameter value.
5. Save and close the file.

Testing Facebook login

1. Run the site's *default.cshtml* page and choose the **Login** button.
2. On the *Login* page, in the **Use another service to log in** section, choose the **Facebook** icon.

   The web page redirects the request to the Facebook login page.

3. Log into a Facebook account.

The code uses the Facebook token to authenticate you and then returns to a page where you can associate your Facebook login with your site's login. Your user name or email address is filled into the **Email** field on the form.

4. Choose the **Associate** button.

   The browser returns to the home page and you are logged in.

Enabling Twitter Logins

1. Browse to the Twitter developers site.
2. Choose the **Create an App** link and then log into the site.
3. On the **Create an Application** form, fill in the **Name** and **Description** fields.
4. In the **WebSite** field, enter the URL of your site (for example, `http://www.example.com`).

   > **NOTE**
   > If you're testing your site locally (using a URL like `http://localhost:12345`), Twitter might not accept the URL. However, you might be able to use the local loopback IP address (for example `http://127.0.0.1:12345`). This simplifies the process of testing your application locally. However, every time the port number of your local site changes, you'll need to update the **WebSite** field of your application.

5. In the **Callback URL** field, enter a URL for the page in your website that you want users to return to after logging into Twitter. For example, to send users to the home page of the Starter Site (which will recognize their logged-in status), enter the same URL that you entered in the **WebSite** field.
6. Accept the terms and choose the **Create your Twitter application** button.
7. On the **My Applications** landing page, choose the application you created.
8. On the **Details** tab, scroll to the bottom and choose the **Create My Access Token** button.
9. On the **Details** tab, copy the **Consumer Key** and **Consumer Secret** values for your application and paste them into a temporary text file. You'll pass these values to the Twitter provider in your website code.
10. Exit the Twitter site.

Now you make changes to two pages in your website so that users will be able to log into the site using their

Twitter accounts.

1. Create or open an ASP.NET Web Pages site that's based on the WebMatrix Starter Site template.
2. Open the *_AppStart.cshtml* page and uncomment the code for the Twitter OAuth provider. The uncommented code block looks like this:

```
OAuthWebSecurity.RegisterTwitterClient(
        consumerKey: "",
        consumerSecret: "");
```

3. Copy the **Consumer Key** value from the Twitter application as the value of the `consumerKey` parameter (inside the quotation marks).
4. Copy the **Consumer Secret** value from the Twitter application as the value of the `consumerSecret` parameter.
5. Save and close the file.

Testing Twitter login

1. Run the *default.cshtml* page of your site and choose the **Login** button.
2. On the *Login* page, in the **Use another service to log in** section, choose the **Twitter** icon.

   The web page redirects the request to a Twitter login page for the application you created.

3. Log into a Twitter account.
4. The code uses the Twitter token to authenticate the user and then returns you to a page where you can associate your login with your website account. Your name or email address is filled into the **Email** field on the form.

5. Choose the **Associate** button.

   The browser returns to the home page and you are logged in.

Using a CAPTCHA to Prevent Bots from Using Your ASP.NET Web Razor) Site

4/10/2020 • 3 minutes to read • Edit Online

by Microsoft

This article explains how to use ReCaptcha (a security measure) to prevent automated programs (bots) from performing tasks in an ASP.NET Web Pages (Razor) website.

What you'll learn:

- How to add a CAPTCHA test to your site.

These are the ASP.NET features introduced in the article:

- The `ReCaptcha` helper.

> **NOTE**
>
> The information in this article applies to ASP.NET Web Pages 1.0 and Web Pages 2.

About CAPTCHAs

Any time you let people register in your site, or even just enter a name and URL (like for a blog comment), you might get a flood of fake names. These are often left by automated programs (bots) that try to leave URLs in every website they can find. (A common motivation is to post the URLs of products for sale.)

You can help make sure that a user is real person and not a computer program by using a *CAPTCHA* to validate users when they register or otherwise enter their name and site. CAPTCHA stands for Completely Automated Public Turing test to tell Computers and Humans Apart. A CAPTCHA is a *challenge-response* test in which the user is asked to do something that is easy for a person to do but hard for an automated program to do. The most common type of CAPTCHA is one where you see some distorted letters and are asked to type them. (The distortion is supposed to make it hard for bots to decipher the letters.)

Adding a ReCaptcha Test

In ASP.NET pages, you can use the `ReCaptcha` helper to render a CAPTCHA test that is based on the ReCaptcha service (http://recaptcha.net). The `ReCaptcha` helper displays an image of two distorted words that users have to enter correctly before the page is validated. The user response is validated by the ReCaptcha.Net service.

1. Register your website at ReCaptcha.Net (http://recaptcha.net). When you've completed registration, you'll get a public key and a private key.

2. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already.

3. If you don't already have a *_AppStart.cshtml* file, in the root folder of a website create a file named *_AppStart.cshtml*.

4. Add the following `Recaptcha` helper settings in the *_AppStart.cshtml* file:

```
@using Microsoft.Web.Helpers;
@{
  // Add the PublicKey and PrivateKey strings with your public
  // and private keys. Obtain your PublicKey and PrivateKey
  // at the ReCaptcha.Net (http://recaptcha.net) website.
  ReCaptcha.PublicKey = "your-public-key";
  ReCaptcha.PrivateKey = "your-private-key";
}
```

5. Set the `PublicKey` and `PrivateKey` properties using your own public and private keys.

6. Save the *_AppStart.cshtml* file and close it.

7. In the root folder of a website, create new page named *Recaptcha.cshtml*.

8. Replace the existing content with the following:

```
@using Microsoft.Web.Helpers;
@{
  var showRecaptcha = true;
  if (IsPost) {
    if (ReCaptcha.Validate()) {
        @:Your response passed!
        showRecaptcha = false;
    }
    else{
      @:Your response didn't pass!
    }
  }
}
<!DOCTYPE html>
<html>
    <head>
        <title>Testing Global Recaptcha Keys</title>
    </head>
    <body>
    <form action="" method="post">
    @if(showRecaptcha == true){
        if(ReCaptcha.PrivateKey != ""){
            <p>@ReCaptcha.GetHtml()</p>
            <input type="submit" value="Submit" />
        }
        else {
            <p>You can get your public and private keys at
            the ReCaptcha.Net website (http://recaptcha.net).
            Then add the keys to the _AppStart.cshtml file.</p>
        }
    }
    </form>
    </body>
</html>
```

9. Run the *Recaptcha.cshtml* page in a browser. If the `PrivateKey` value is valid, the page displays the ReCaptcha control and a button. If you had not set the keys globally in *_AppStart.html*, the page would display an error.

10. Enter the words for the test. If you pass the ReCaptcha test, you see a message to that effect. Otherwise you see an error message and the ReCaptcha control is redisplayed.

NOTE

If your computer is on a domain that uses proxy server, you might need to configure the `defaultproxy` element of the *Web.config* file. The following example shows a *Web.config* file with the `defaultproxy` element configured to enable the ReCaptcha service to work.

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <system.net>
      <defaultProxy>
         <proxy
            usesystemdefault = "false"
            proxyaddress="http://myProxy.MyDomain.com"
            bypassonlocal="true"
            autoDetect="False"
         />
      </defaultProxy>
   </system.net>
</configuration>
```

Caching Data in an ASP.NET Web Pages (Razor) Site for Better Performance

2/20/2020 • 5 minutes to read • Edit Online

by Tom FitzMacken

This article explains how to use a helper to cache information for faster performance in an ASP.NET Web Pages (Razor) website. You can speed up your website by having it store — that is, cache — the results of data that ordinarily would take considerable time to retrieve or process and that does not change often.

What you'll learn:

- How to use caching to improve the responsiveness of your website.

These are the ASP.NET features introduced in the article:

- The `WebCache` helper.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2.

Every time someone requests a page from your site, the web server has to do some work in order to fulfill the request. For some of your pages, the server might have to perform tasks that take a (comparatively) long time, such as retrieving data from a database. Even if these tasks don't take long in absolute terms, if your site experiences a lot of traffic, a whole series of individual requests that cause the web server to perform the complicated or slow task can add up to a lot of work. This can ultimately affect the performance of the site.

One way to improve the performance of your website in circumstances like this is to cache data. If your site gets repeated requests for the same information, and the information does not need to be modified for each person, and it's not time sensitive, instead of re-fetching or recalculating it, you can fetch the data once and then store the results. The next time a request comes in for that information, you just get it out of the cache.

In general, you cache information that doesn't change frequently. When you put information in the cache, it's stored in memory on the web server. You can specify how long it should be cached, from seconds to days. When the caching period expires, the information is automatically removed from the cache.

> **NOTE**
>
> Entries in the cache might be removed for reasons other than that they've expired. For example, the web server might temporarily run low on memory, and one way it can reclaim memory is by throwing entries out of the cache. As you'll see, even if you've put information into the cache, you have to check to be sure it's still there when you need it.

Imagine your website has a page that displays the current temperature and weather forecast. To get this type of information, you might send a request to an external service. Since this information doesn't change much (within a two-hour time period, for example) and since external calls require time and bandwidth, it's a good candidate for caching.

Adding Caching to a Page

ASP.NET includes a `WebCache` helper that makes it easy to add caching to your site and add data to the cache. In this procedure, you'll create a page that caches the current time. This isn't a real-world example, since the current time is something that does change often, and that moreover isn't complex to calculate. However, it's a good way to illustrate caching in action.

1. Add a new page named *WebCache.cshtml* to the website.

2. Add the following code and markup to the page:

```
@{
    var cacheItemKey = "CachedTime";
    var cacheHit = true;
    var time = WebCache.Get(cacheItemKey);

    if (time == null) {
        cacheHit = false;
    }

    if (cacheHit == false) {
        time = @DateTime.Now;
        WebCache.Set(cacheItemKey, time, 1, false);
    }
}
<!DOCTYPE html>
<html>
<head>
    <title>WebCache Helper Sample</title>
</head>
<body>
    <div>
        @if (cacheHit) {
            @:Found the time data in the cache.
        } else {
            @:Did not find the time data in the cache.
        }
    </div>
    <div>
        This page was cached at @time.
    </div>
</body>
</html>
```

When you cache data, you put it into the cache using a name this is unique across the website. In this case, you'll use a cache entry named `CachedTime`. This is the `cacheItemKey` shown in the code example.

The code first reads the `CachedTime` cache entry. If a value is returned (that is, if the cache entry isn't null), the code just sets the value of the time variable to the cache data.

However, if the cache entry doesn't exist (that is, it's null), the code sets the time value, adds it to the cache, and sets an expiration value to one minute. After one minute, the cache entry is discarded. (The default expiration value for an item in the cache is 20 minutes.) The command `WebCache.Set(cacheItemKey, time, 1, false)` shows how to add the current time value to the cache and set its expiration to 1 minute. Setting the *slidingExpiration* parameter to `false` means the expiration time is not renewed each time it is requested. It will expire exactly 1 minute after it was originally added to the cache. If you set this value to `true` the 1 minute expiration time is reset each time the value is requested from the cache.

This code illustrates the pattern you should always use when you cache data. Before you get something out of the cache, always check first whether the `WebCache.Get` method has returned null. Remember that the

cache entry might have expired or might have been removed for some other reason, so any given entry is never guaranteed to be in the cache.

3. Run *WebCache.cshtml* in a browser. (Make sure the page is selected in the **Files** workspace before you run it.) The first time you request the page, the time data isn't in the cache, and the code has to add the time value to the cache.

4. Refresh *WebCache.cshtml* in the browser. This time, the time data is in the cache. Notice that the time hasn't changed since the last time you viewed the page.

5. Wait one minute for the cache to be emptied, and then refresh the page. The page again indicates that the time data wasn't found in the cache, and the updated time is added to the cache.

Tracking Visitor Information (Analytics) for an ASP.NET Web Pages (Razor) Site

2/20/2020 • 4 minutes to read • Edit Online

by Tom FitzMacken

This article describes how to use a helper to add website analytics to pages in an ASP.NET Web Pages (Razor) website.

What you'll learn:

- How to send information about your website traffic to an analytics provider.

These are the ASP.NET programming features introduced in the article:

- The `Analytics` helper.

Software versions used in the tutorial

- ASP.NET Web Pages (Razor) 2
- ASP.NET Web Helpers Library (NuGet package)

Analytics is a general term for technology that measures traffic on your website so you can understand how people use the site. Many analytics services are available, including services from Google, Yahoo, StatCounter, and others.

The way analytics works is that you sign up for an account with the analytics provider, where you register the site that you want to track. The provider sends you a snippet of JavaScript code that includes an ID or tracking code for your account. You add the JavaScript snippet to the web pages on the site that you want to track. (You typically add the analytics snippet to a footer or layout page or other HTML markup that appears on every page in your site.) When users request a page that contains one of these JavaScript snippets, the snippet sends information about the current page to the analytics provider, who records various details about the page.

When you want to have a look at your site statistics, you log into the analytics provider's website. You can then view all sorts of reports about your site, like:

- The number of page views for individual pages. This tells you (roughly) how many people are visiting the site, and which pages on your site are the most popular.
- How long people spend on specific pages. This can tell you things like whether your home page is keeping people's interest.
- What sites people were on before they visited your site. This helps you understand whether your traffic is coming from links, from searches, and so on.
- When people visit your site and how long they stay.
- What countries your visitors are from.
- What browsers and operating systems your visitors are using.

Using a Helper to Add Analytics to a Page

ASP.NET Web Pages includes several analytics helpers (`Analytics.GetGoogleHtml` , `Analytics.GetYahooHtml` , and `Analytics.GetStatCounterHtml`) that make it easy to manage the JavaScript snippets used for analytics. Instead of figuring out how and where to put the JavaScript code, all you have to do is add the helper to a page. The only information you need to provide is your account name, ID, or tracking code. (For StatCounter, you also have to provide a few additional values.)

In this procedure, you'll create a layout page that uses the `GetGoogleHtml` helper. If you already have an account with one of the other analytics providers, you can use that account instead and make slight adjustments as needed.

> **NOTE**
> When you create an analytics account, you register the URL of the site that you want to be tracking. If you're testing everything on your local computer, you won't be tracking actual traffic (the only traffic is you), so you won't be able to record and view site statistics. But this procedure shows how you add an analytics helper to a page. When you publish your site, the live site will send information to your analytics provider.

1. Add the ASP.NET Web Helpers Library to your website as described in Installing Helpers in an ASP.NET Web Pages Site, if you haven't already added it.

2. Create an account with Google Analytics and record the account name.

3. Create a layout page named *Analytics.cshtml* and add the following markup:

```
@using Microsoft.Web.Helpers;
<!DOCTYPE html>
<html>
  <head>
    <title>Analytics Test</title>
  </head>
  <body>
    <h1>Analytics Test Page</h1>
    <p>Lorem ipsum dolor sit amet, consectetur adipisicing elit,
    sed do eiusmod tempor incididunt ut labore et dolore magna aliqua. </p>
    <div id="footer">
      &copy; 2012 MySite
    </div>
    @Analytics.GetGoogleHtml("myaccount")
  </body>
</html>
```

> **NOTE**
> You must place the call to the `Analytics` helper in the body of your web page (before the `</body>` tag). Otherwise, the browser will not run the script.

If you're using a different analytics provider, use one of the following helpers instead:

- (Yahoo) `@Analytics.GetYahooHtml("myaccount")`
- (StatCounter) `@Analytics.GetStatCounterHtml("project", "security")`

4. Replace `myaccount` with the name of the account, ID, or tracking code that you created in step 1.

5. Run the page in the browser. (Make sure the page is selected in the **Files** workspace before you run it.)

6. In the browser, view the page source. You'll be able to see the rendered analytics code:

```
<!DOCTYPE html>
<html>
  <head>
    <title>Analytics Test</title>
  </head>
  <body>
    <h1>Analytics Test Page</h1>
    <p>Lorem ipsum dolor sit amet, consectetur adipisicing elit,
    sed do eiusmod tempor incididunt ut labore et dolore magna aliqua.</p>
    <div id="footer">
      &copy; 2012 MySite
    </div>
    <script type="text/javascript">
      var gaJsHost = (("https:" == document.location.protocol) ? "https://ssl." : "http://www.");
      document.write(unescape("%3Cscript src='" + gaJsHost + "google-analytics.com/ga.js'
type='text/javascript'%3E%3C/script%3E"));
    </script>
    <script type="text/javascript">
      try{
      var pageTracker = _gat._getTracker("myaccount");
      pageTracker._trackPageview();
      } catch(err) {}
    </script>
  </body>
</html>
```

7. Log onto the Google Analytics site and examine the statistics for your site. If you're running the page on a live site, you see an entry that logs the visit to your page.

Bundling and Minifying Assets in an ASP.NET Web Pages (Razor) Site

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Bundling and minification are ways to make your site faster. Bundling lets you combine multiple JavaScript (*.js*) files or multiple cascading style sheet (*.css*) files so that they can be downloaded as a unit, rather than one at a time. Minification squeezes out whitespace and performs other types of compression to make the downloaded files as small a possible.

> **NOTE**
>
> The RC release of ASP.NET Web Pages 2 does not support bundling and minification because the package that contains the required elements is not yet available in Microsoft WebMatrix. We apologize for this inconvenience. The package is expected to be available in the final release of ASP.NET Web Pages 2 and WebMatrix 2.

ASP.NET Web Pages (Razor) API Quick Reference

2/20/2020 • 13 minutes to read • Edit Online

by Tom FitzMacken

> This page contains a list with brief examples of the most commonly used objects, properties, and methods for programming ASP.NET Web Pages with Razor syntax.
>
> Descriptions marked with "(v2)" were introduced in ASP.NET Web Pages version 2.
>
> For API reference documentation, see the ASP.NET Web Pages Reference Documentation on MSDN.
>
> ## Software versions
>
> - ASP.NET Web Pages (Razor) 3
>
> This tutorial also works with ASP.NET Web Pages 2 and ASP.NET Web Pages 1.0 (except for features marked v2).

This page contains reference information for the following:

- Classes
- Data
- Helpers
- Validation

Classes

`AppState[key], AppState[index],App`

Contains data that can be shared by any pages in the application. You can use the dynamic `App` property to access the same data, as in the following example:

```
AppState["FavoriteColor"] = "red";
AppState[1] = "apples";
App.MyGreeting = "Good morning";
// Displays the value assigned to AppData[1] in the page.
@App[1]
// Displays the value assigned to App.MyGreeting.
@App.MyGreeting
```

`AsBool(), AsBool(true|false)`

Converts a string value to a Boolean value (true/false). Returns false or the specified value if the string does not represent true/false.

```
bool b = stringValue.AsBool();
```

`AsDateTime(), AsDateTime(value)`

Converts a string value to date/time. Returns `DateTime.MinValue` or the specified value if the string does not represent a date/time.

```
DateTime dt = stringValue.AsDateTime();
```

`AsDecimal(), AsDecimal(value)`

Converts a string value to a decimal value. Returns 0.0 or the specified value if the string does not represent a decimal value.

```
decimal d = stringValue.AsDecimal();
```

`AsFloat(), AsFloat(value)`

Converts a string value to a float. Returns 0.0 or the specified value if the string does not represent a decimal value.

```
float d = stringValue.AsFloat();
```

`AsInt(), AsInt(value)`

Converts a string value to an integer. Returns 0 or the specified value if the string does not represent an integer.

```
int i = stringValue.AsInt();
```

`Href(path [, param1 [, param2]])`

Creates a browser-compatible URL from a local file path, with optional additional path parts.

```
<a href="@Href("~/Folder/File")">Link to My File</a>
<a href="@Href("~/Product", "Tea")">Link to Product</a>
```

`Html.Raw(value)`

Renders *value* as HTML markup instead of rendering it as HTML-encoded output.

```
@* Inserts markup into the page. *@
@Html.Raw("<div>Hello <em>world</em>!</div>")
```

`IsBool(), IsDateTime(), IsDecimal(), IsFloat(), IsInt()`

Returns true if the value can be converted from a string to the specified type.

```
var isint = stringValue.IsInt();
```

`IsEmpty()`

Returns true if the object or variable has no value.

```
if (Request["companyname"].IsEmpty()) {
    @:Company name is required.<br />
}
```

`IsPost`

Returns true if the request is a POST. (Initial requests are usually a GET.)

```
if (IsPost) { Response.Redirect("Posted"); }
```

`Layout`

Specifies the path of a layout page to apply to this page.

```
Layout = "_MyLayout.cshtml";
```

`PageData[key], PageData[index],Page`

Contains data shared between the page, layout pages, and partial pages in the current request. You can use the dynamic `Page` property to access the same data, as in the following example:

```
PageData["FavoriteColor"] = "red";
PageData[1] = "apples";
Page.MyGreeting = "Good morning";
// Displays the value assigned to PageData[1] in the page.
@Page[1]
// Displays the value assigned to Page.MyGreeting.
@Page.MyGreeting
```

`RenderBody()`

(Layout pages) Renders the content of a content page that is not in any named sections.

```
@RenderBody()
```

`RenderPage(path, values)`

`RenderPage(path[,param1 [, param2]])`

Renders a content page using the specified path and optional extra data. You can get the values of the extra parameters from `PageData` by position (example 1) or key (example 2).

```
RenderPage("_MySubPage.cshtml", "red", 123, "apples")
RenderPage("_MySubPage.cshtml", new { color = "red", number = 123, food = "apples" })
```

`RenderSection(sectionName [, required = true|false])`

(Layout pages) Renders a content section that has a name. Set *required* to false to make a section optional.

```
@RenderSection("header")
```

`Request.Cookies[key]`

Gets or sets the value of an HTTP cookie.

```
var cookieValue = Request.Cookies["myCookie"].Value;
```

`Request.Files[key]`

Gets the files that were uploaded in the current request.

```
Request.Files["postedFile"].SaveAs(@"MyPostedFile");
```

`Request.Form[key]`

Gets data that was posted in a form (as strings). `Request[key]` checks both the `Request.Form` and the `Request.QueryString` collections.

```
var formValue = Request.Form["myTextBox"];
// This call produces the same result.
var formValue = Request["myTextBox"];
```

`Request.QueryString[key]`

Gets data that was specified in the URL query string. `Request[key]` checks both the `Request.Form` and the `Request.QueryString` collections.

```
var queryValue = Request.QueryString["myTextBox"];
// This call produces the same result.
var queryValue = Request["myTextBox"];
```

`Request.Unvalidated(key)`

`Request.Unvalidated().QueryString|Form|Cookies|Headers[key]`

Selectively disables request validation for a form element, query-string value, cookie, or header value. Request validation is enabled by default and prevents users from posting markup or other potentially dangerous content.

```
// Call the method directly to disable validation on the specified item from
// one of the Request collections.
Request.Unvalidated("userText");

// You can optionally specify which collection the value is from.
var prodID = Request.Unvalidated().QueryString["productID"];
var richtextValue = Request.Unvalidated().Form["richTextBox1"];
var cookie = Request.Unvalidated().Cookies["mostRecentVisit"];
```

`Response.AddHeader(name, value)`

Adds an HTTP server header to the response.

```
// Adds a header that requests client browsers to use basic authentication.
Response.AddHeader("WWW-Authenticate", "BASIC");
```

`Response.OutputCache(seconds [, sliding] [, varyByParams])`

Caches the page output for a specified time. Optionally set *sliding* to reset the timeout on each page access and *varyByParams* to cache different versions of the page for each different query string in the page request.

```
Response.OutputCache(60);
Response.OutputCache(3600, true);
Response.OutputCache(10, varyByParams : new[] {"category","sortOrder"});
```

`Response.Redirect(path)`

Redirects the browser request to a new location.

```
Response.Redirect("~/Folder/File");
```

`Response.SetStatus(httpStatusCode)`

Sets the HTTP status code sent to the browser.

```
Response.SetStatus(HttpStatusCode.Unauthorized);
Response.SetStatus(401);
```

`Response.WriteBinary(data [, mimetype])`

Writes the contents of *data* to the response with an optional MIME type.

```
Response.WriteBinary(image, "image/jpeg");
```

`Response.WriteFile(file)`

Writes the contents of a file to the response.

```
Response.WriteFile("file.ext");
```

`@section(sectionName) {content }`

(Layout pages) Defines a content section that has a name.

```
@section header { <div>Header text</div> }
```

`Server.HtmlDecode(htmlText)`

Decodes a string that is HTML encoded.

```
var htmlDecoded = Server.HtmlDecode("&lt;html&gt;");
```

`Server.HtmlEncode(text)`

Encodes a string for rendering in HTML markup.

```
var htmlEncoded = Server.HtmlEncode("<html>");
```

`Server.MapPath(virtualPath)`

Returns the server physical path for the specified virtual path.

```
var dataFile = Server.MapPath("~/App_Data/data.txt");
```

`Server.UrlDecode(urlText)`

Decodes text from a URL.

```
var urlDecoded = Server.UrlDecode("url%20data");
```

`Server.UrlEncode(text)`

Encodes text to put in a URL.

```
var urlEncoded = Server.UrlEncode("url data");
```

`Session[key]`

Gets or sets a value that exists until the user closes the browser.

```
Session["FavoriteColor"] = "red";
```

`ToString()`

Displays a string representation of the object's value.

```
<p>It is now @DateTime.Now.ToString()</p>
```

`UrlData[index]`

Gets additional data from the URL (for example, */MyPage/ExtraData*).

```
var pathInfo = UrlData[0];
```

`WebSecurity.ChangePassword(userName,currentPassword,newPassword)`

Changes the password for the specified user.

```
var success = WebSecurity.ChangePassword("my-username",
    "current-password", "new-password");
```

`WebSecurity.ConfirmAccount(accountConfirmationToken)`

Confirms an account using the account confirmation token.

```
var confirmationToken = Request.QueryString["ConfirmationToken"];
if(WebSecurity.ConfirmAccount(confirmationToken)) {
      //...
}
```

`WebSecurity.CreateAccount(userName, password`

`[, requireConfirmationToken = true|false])`

Creates a new user account with the specified user name and password. To require a confirmation token, pass true for *requireConfirmationToken.*

```
WebSecurity.CreateAccount("my-username", "secretpassword");
```

`WebSecurity.CurrentUserId`

Gets the integer identifier for the currently logged-in user.

```
var userId = WebSecurity.CurrentUserId;
```

`WebSecurity.CurrentUserName`

Gets the name for the currently logged-in user.

```
var welcome = "Hello " + WebSecurity.CurrentUserName;
```

`WebSecurity.GeneratePasswordResetToken(username`

`[, tokenExpirationInMinutesFromNow])`

Generates a password-reset token that can be sent in email to a user so that the user can reset the password.

```
var resetToken = WebSecurity.GeneratePasswordResetToken("my-username");
var message = "Visit http://example.com/reset-password/" + resetToken +
    " to reset your password";
WebMail.Send(..., message);
```

`WebSecurity.GetUserId(userName)`

Returns the user ID from the user name.

```
var userId = WebSecurity.GetUserId(userName);
```

`WebSecurity.IsAuthenticated`

Returns true if the current user is logged in.

```
if(WebSecurity.IsAuthenticated) {...}
```

`WebSecurity.IsConfirmed(userName)`

Returns true if the user has been confirmed (for example, through a confirmation email).

```
if(WebSecurity.IsConfirmed("joe@contoso.com")) { ... }
```

`WebSecurity.IsCurrentUser(userName)`

Returns true if the current user's name matches the specified user name.

```
if(WebSecurity.IsCurrentUser("joe@contoso.com")) { ... }
```

`WebSecurity.Login(userName,password[, persistCookie])`

Logs the user in by setting an authentication token in the cookie.

```
if(WebSecurity.Login("username", "password")) { ... }
```

`WebSecurity.Logout()`

Logs the user out by removing the authentication token cookie.

```
WebSecurity.Logout();
```

`WebSecurity.RequireAuthenticatedUser()`

If the user is not authenticated, sets the HTTP status to 401 (Unauthorized).

```
WebSecurity.RequireAuthenticatedUser();
```

`WebSecurity.RequireRoles(roles)`

If the current user is not a member of one of the specified roles, sets the HTTP status to 401 (Unauthorized).

```
WebSecurity.RequireRoles("Admin", "Power Users");
```

`WebSecurity.RequireUser(userId)`

`WebSecurity.RequireUser(userName)`

If the current user is not the user specified by *username*, sets the HTTP status to 401 (Unauthorized).

```
WebSecurity.RequireUser("joe@contoso.com");
```

`WebSecurity.ResetPassword(passwordResetToken,newPassword)`

If the password reset token is valid, changes the user's password to the new password.

```
WebSecurity.ResetPassword( "A0F36BFD9313", "new-password")
```

Data

`Database.Execute(SQLstatement [,parameters]`

Executes *SQLstatement* (with optional parameters) such as INSERT, DELETE, or UPDATE and returns a count of affected records.

```
db.Execute("INSERT INTO Data (Name) VALUES ('Smith')");

db.Execute("INSERT INTO Data (Name) VALUES (@0)", "Smith");
```

`Database.GetLastInsertId()`

Returns the identity column from the most recently inserted row.

```
db.Execute("INSERT INTO Data (Name) VALUES ('Smith')");
var id = db.GetLastInsertId();
```

`Database.Open(filename)`

`Database.Open(connectionStringName)`

Opens either the specified database file or the database specified using a named connection string from the *Web.config* file.

```
// Note that no filename extension is specified.
var db = Database.Open("SmallBakery"); // Opens SmallBakery.sdf in App_Data
// Opens a database by using a named connection string.
var db = Database.Open("SmallBakeryConnectionString");
```

`Database.OpenConnectionString(connectionString)`

Opens a database using the connection string. (This contrasts with `Database.Open`, which uses a connection string name.)

```
var db = Database.OpenConnectionString("Data Source=|DataDirectory|\SmallBakery.sdf");
```

`Database.Query(SQLstatement[,parameters])`

Queries the database using *SQLstatement* (optionally passing parameters) and returns the results as a collection.

```
foreach (var result in db.Query("SELECT * FROM PRODUCT")) {<p>@result.Name</p>}

foreach (var result = db.Query("SELECT * FROM PRODUCT WHERE Price > @0", 20))
   { <p>@result.Name</p> }
```

`Database.QuerySingle(SQLstatement [, parameters])`

Executes *SQLstatement* (with optional parameters) and returns a single record.

```
var product = db.QuerySingle("SELECT * FROM Product WHERE Id = 1");

var product = db.QuerySingle("SELECT * FROM Product WHERE Id = @0", 1);
```

`Database.QueryValue(SQLstatement [, parameters])`

Executes *SQLstatement* (with optional parameters) and returns a single value.

```
var count = db.QueryValue("SELECT COUNT(*) FROM Product");

var count = db.QueryValue("SELECT COUNT(*) FROM Product WHERE Price > @0", 20);
```

Helpers

`Analytics.GetGoogleHtml(webPropertyId)`

Renders the Google Analytics JavaScript code for the specified ID.

```
@Analytics.GetGoogleHtml("MyWebPropertyId")
```

`Analytics.GetStatCounterHtml(project,security)`

Renders the StatCounter Analytics JavaScript code for the specified project.

```
@Analytics.GetStatCounterHtml(89, "security")
```

`Analytics.GetYahooHtml(account)`

Renders the Yahoo Analytics JavaScript code for the specified account.

```
@Analytics.GetYahooHtml("myaccount")
```

`Bing.SearchBox([boxWidth])`

Passes a search to Bing. To specify the site to search and a title for the search box, you can set the `Bing.SiteUrl` and `Bing.SiteTitle` properties. Normally you set these properties in the *_AppStart* page.

```
@Bing.SearchBox() @* Searches the web.*@
```

```
@{
   Bing.SiteUrl = "www.asp.net";  @* Limits search to the www.asp.net site. *@
}
@Bing.SearchBox()
```

`Chart(width,height [, template] [, templatePath])`

Initializes a chart.

```
@{
   var myChart = new Chart(width: 600, height: 400);
}
```

`Chart.AddLegend([title] [, name])`

Adds a legend to a chart.

```
@{
var myChart = new Chart(width: 600, height: 400)
    .AddLegend("Basic Chart")
    .AddSeries(
        name: "Employee",
        xValue: new[] {  "Peter", "Andrew", "Julie", "Mary", "Dave" },
        yValues: new[] { "2", "6", "4", "5", "3" })
    .Write();
}
```

`Chart.AddSeries([name] [, chartType] [, chartArea]`

`[, axisLabel] [, legend] [, markerStep] [, xValue]`
`[, xField] [, yValues] [, yFields] [, options])`

Adds a series of values to the chart.

```
@{
var myChart = new Chart(width: 600, height: 400)
    .AddSeries(
        name: "Employee",
        xValue: new[] {  "Peter", "Andrew", "Julie", "Mary", "Dave" },
        yValues: new[] { "2", "6", "4", "5", "3" })
    .Write();
}
```

`Crypto.Hash(string [, algorithm])`

`Crypto.Hash(bytes [, algorithm])`

Returns a hash for the specified data. The default algorithm is `sha256`.

```
@Crypto.Hash("data")
```

`Facebook.LikeButton(href [, buttonLayout] [, showFaces] [, width] [, height]`

`[, action] [, font] [, colorScheme] [, refLabel])`

Lets Facebook users make a connection to pages.

```
@Facebook.LikeButton("www.asp.net")
```

`FileUpload.GetHtml([initialNumberOfFiles] [, allowMoreFilesToBeAdded]`

`[, includeFormTag] [, addText] [, uploadText])`

Renders UI for uploading files.

```
@FileUpload.GetHtml(initialNumberOfFiles:1, allowMoreFilesToBeAdded:false,
  includeFormTag:true, uploadText:"Upload")
```

`GamerCard.GetHtml(gamerTag)`

Renders the specified Xbox gamer tag.

```
@GamerCard.GetHtml("joe")
```

`Gravatar.GetHtml(email [, imageSize] [, defaultImage] [, rating]`

`[, imageExtension] [, attributes])`

Renders the Gravatar image for the specified email address.

```
@Gravatar.GetHtml("joe@contoso.com")
```

`Json.Encode(object)`

Converts a data object to a string in the JavaScript Object Notation (JSON) format.

```
var myJsonString = Json.Encode(dataObject);
```

`Json.Decode(string)`

Converts a JSON-encoded input string to a data object that you can iterate over or insert into a database.

```
var myJsonObj = Json.Decode(jsonString);
```

`LinkShare.GetHtml(pageTitle[, pageLinkBack] [, twitterUserName]`

`[, additionalTweetText] [, linkSites])`

Renders social networking links using the specified title and optional URL.

```
@LinkShare.GetHtml("ASP.NET Web Pages Samples")
@LinkShare.GetHtml("ASP.NET Web Pages Samples", "http://www.asp.net")
```

`ModelStateDictionary.AddError(key, errorMessage)`

Associates an error message with a form field. Use the `ModelState` helper to access this member.

```
ModelState.AddError("email", "Enter an email address");
```

`ModelStateDictionary.AddFormError(errorMessage)`

Associates an error message with a form. Use the `ModelState` helper to access this member.

```
ModelState.AddFormError("Password and confirmation password do not match.");
```

`ModelStateDictionary.IsValid`

Returns true if there are no validation errors. Use the `ModelState` helper to access this member.

```
if (ModelState.IsValid) { // Save the form to the database }
```

`ObjectInfo.Print(value [, depth] [, enumerationLength])`

Renders the properties and values of an object and any child objects.

```
@ObjectInfo.Print(person)
```

`Recaptcha.GetHtml([, publicKey] [, theme] [, language] [, tabIndex])`

Renders the reCAPTCHA verification test.

```
@ReCaptcha.GetHtml()
```

`ReCaptcha.PublicKey`

`ReCaptcha.PrivateKey`

Sets public and private keys for the reCAPTCHA service. Normally you set these properties in the *_AppStart* page.

```
ReCaptcha.PublicKey = "your-public-recaptcha-key";
ReCaptcha.PrivateKey = "your-private-recaptcha-key";
```

`ReCaptcha.Validate([, privateKey])`

Returns the result of the reCAPTCHA test.

```
if (ReCaptcha.Validate()) {
   // Test passed.
}
```

`ServerInfo.GetHtml()`

Renders status information about ASP.NET Web Pages.

```
@ServerInfo.GetHtml()
```

`Twitter.Profile(twitterUserName)`

Renders a Twitter stream for the specified user.

```
@Twitter.Profile("billgates")
```

`Twitter.Search(searchQuery)`

Renders a Twitter stream for the specified search text.

```
@Twitter.Search("asp.net")
```

`Video.Flash(filename [, width, height])`

Renders a Flash video player for the specified file with optional width and height.

```
@Video.Flash("test.swf", "100", "100")
```

`Video.MediaPlayer(filename [, width, height])`

Renders a Windows Media player for the specified file with optional width and height.

```
@Video.MediaPlayer("test.wmv", "100", "100")
```

`Video.Silverlight(filename, width, height)`

Renders a Silverlight player for the specified *.xap* file with required width and height.

```
@Video.Silverlight("test.xap", "100", "100")
```

`WebCache.Get(key)`

Returns the object specified by *key*, or null if the object is not found.

```
var username = WebCache.Get("username")
```

`WebCache.Remove(key)`

Removes the object specified by *key* from the cache.

```
WebCache.Remove("username")
```

`WebCache.Set(key, value [, minutesToCache] [, slidingExpiration])`

Puts *value* into the cache under the name specified by *key*.

```
WebCache.Set("username", "joe@contoso.com ")
```

`WebGrid(data)`

Creates a new `WebGrid` object using data from a query.

```
var db = Database.Open("SmallBakery");
var grid = new WebGrid(db.Query("SELECT * FROM Product"));
```

`WebGrid.GetHtml()`

Renders markup to display data in an HTML table.

```
@grid.GetHtml()// The 'grid' variable is set when WebGrid is created.
```

`WebGrid.Pager()`

Renders a pager for the `WebGrid` object.

```
@grid.Pager() // The 'grid' variable is set when WebGrid is created.
```

`WebImage(path)`

Loads an image from the specified path.

```
var image = new WebImage("test.png");
```

`WebImage.AddImagesWatermark(image)`

Adds the specified image as a watermark.

```
WebImage photo = new WebImage("test.png");
WebImage watermarkImage = new WebImage("logo.png");
photo.AddImageWatermark(watermarkImage);
```

`WebImage.AddTextWatermark(text)`

Adds the specified text to the image.

```
image.AddTextWatermark("Copyright")
```

`WebImage.FlipHorizontal()`

`WebImage.FlipVertical()`

Flips the image horizontally or vertically.

```
image.FlipHorizontal();
image.FlipVertical();
```

`WebImage.GetImageFromRequest()`

Loads an image when an image is posted to a page during a file upload.

```
var image = WebImage.GetImageFromRequest();
```

`WebImage.Resize(width,height)`

Resizes an the image.

```
image.Resize(100, 100);
```

`WebImage.RotateLeft()`

`WebImage.RotateRight()`

Rotates the image to the left or the right.

```
image.RotateLeft();
image.RotateRight();
```

`WebImage.Save(path [, imageFormat])`

Saves the image to the specified path.

```
image.Save("test.png");
```

`WebMail.Password`

Sets the password for the SMTP server. Normally you set this property in the *_AppStart* page.

```
WebMail.Password = "password";
```

`WebMail.Send(to, subject, body [, from] [, cc] [, filesToAttach] [, isBodyHtml]`

`[, additionalHeaders])`

Sends an email message.

```
WebMail.Send("touser@contoso.com", "subject", "body of message",
    "fromuser@contoso.com");
```

`WebMail.SmtpServer`

Sets the SMTP server name. Normally you set this property in the *_AppStart* page.

```
WebMail.SmtpServer = "smtp.mailserver.com";
```

`WebMail.UserName`

Sets the user name for the SMTP server. Normally you should set this property in the *_AppStart* page.

```
WebMail.UserName = "Joe";
```

Validation

`Html.ValidationMessage(field)`

(v2) Renders a validation error message for the specified field.

```
<input type="text"
    name="dateOfBirth"
    value="" />
@Html.ValidationMessage("dateOfBirth")
```

`Html.ValidationSummary([message])`

(v2) Displays a list of all validation errors.

```
@Html.ValidationSummary()

@Html.ValidationSummary("The following validation errors occurred:")
```

`Validation.Add(field, validationType)`

(v2) Registers a user input element for the specified type of validation.

```
Validation.Add("dateOfBirth", Validator.DateTime("Date of birth was not valid"));
Validation.Add("quantity", Validator.Integer("Enter a number"));
Validation.Add("confirmPassword",
    Validator.EqualsTo("password", "Passwords must match."));
```

`Validation.ClassFor(field)`

(v2) Dynamically renders CSS class attributes for client-side validation so that you can format validation error messages. (Requires that you reference the appropriate client-script libraries and that you define CSS classes.)

```
<head>
  <script
    src="https://ajax.aspnetcdn.com/ajax/jQuery/jquery-1.6.2.js">
  </script>
  <script
    src="https://ajax.aspnetcdn.com/ajax/jquery.validate/1.8.1/jquery.validate.js">
  </script>
  <script
    src="~/Scripts/jquery.validate.unobtrusive.js">
  </script>

  <style>
    input-validation-error{ /* style rules  */ }
    field-validation-error{ /* style rules  */ }
    validation-summary-errors{ /* style rules  */ }
    field-validation-valid{ /* style rules  */ }
    input-validation-valid{ /* style rules  */ }
    validation-summary-valid{ /* style rules  */ }
  </style>
</head>

...

<input
    type="text"
    name="firstName"
    @Validation.For("firstName") @Validation.ClassFor("firstName")  />
```

`Validation.For(field)`

(v2) Enables client-side validation for the user input field. (Requires that you reference the appropriate client-script libraries.)

```
<head>
  <script
    src="https://ajax.aspnetcdn.com/ajax/jQuery/jquery-1.6.2.js">
  </script>
  <script
    src="https://ajax.aspnetcdn.com/ajax/jquery.validate/1.8.1/jquery.validate.js">
  </script>
  <script
    src="~/Scripts/jquery.validate.unobtrusive.js">
  </script>
</head>

...

<input
    type="text"
    name="firstName"
    @Validation.For("firstName") />
```

`Validation.IsValid()`

(v2) Returns true if all user input elements that are registred for validation contain valid values.

```
if(IsPost){
    if (Validation.IsValid()) {
        // Process input
    }
}
```

`Validation.RequireField(field[, errorMessage])`

(v2) Specifies that users must provide a value for the user input element.

```
Validation.RequireField("dateOfBirth", "Date of birth is required");
```

`Validation.RequireFields(field1[, field12, field3, ...])`

(v2) Specifies that users must provide values for each of the user input elements. This method does not let you specify a custom error message.

```
Validation.RequireFields("firstName", "lastName", "dateOfBirth");
```

`Validator.DateTime ([error message])`

`Validator.Decimal([error message])`
`Validator.EqualsTo(otherField,[error message])`
`Validator.Float([error message])`
`Validator.Integer([error message])`
`Validator.Range(min,max [, error message])`
`Validator.RegEx(pattern[, error message])`
`Validator.Required([error message])`
`Validator.StringLength(length)`
`Validator.Url([error message])`

(v2) Specifies a validation test when you use the `Validation.Add` method.

```
Validation.Add("dateOfBirth", Validator.DateTime("Date of birth was not valid"));
Validation.Add("quantity", Validator.Integer("Enter a number"));
Validation.Add("confirmPassword", Validator.EqualsTo("password",
    "Passwords must match."));
```

Web Pages Releases

- Running Different Versions of ASP.NET Web Pages Side by Side

What's New in ASP.NET Web Pages 3.2

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

This topic describes what's new for ASP.NET Web Pages 3.2, Web Pages 3.2.2 and Web Pages 3.2.3 beta1

ASP.NET Web Pages 3.2

This release fixes a bug and introduces one new feature.

Download

The runtime features are released as NuGet packages on the NuGet gallery. All the runtime packages follow the Semantic Versioning specification. The ASP.NET Web Pages 3.2 package has the following version: "3.2.0". You can install or update these packages through NuGet. The release also includes corresponding localized packages on NuGet.

You can install or update to the released NuGet packages by using the NuGet Package Manager Console:

```
Install-Package Microsoft.AspNet.WebPages -Version 3.2.0
```

New Feature and Bug Fix

We fixed one bug and made one minor feature enhancement in this release. You can find the query for the same here.

ASP.NET Web Pages 3.2.2

This release rolls-up the change in the ASP.NET Web Pages 3.2.1 Beta release which provides a significant performance improvement in rendering large razor pages. SeeCodeplex Issue 585. This release aligns with the MVC 5.2.2 packages which will now depend on this version.

We worked with the MSN team on rendering large pages. When pages render over 80 Kilobytes of data, we end up with objects on the large object heap. When multiple layers of layouts are used this effect can be multiplied.

The result on the server is extra CPU usage, longer retention of memory, and even long pauses during Gen 2 cleanup in the garbage collector.

Below is a table demonstrating the results of analyzing a perfview for a run. The CPU is held constant at about 68%, while large pages are being rendered. The table shows that the number of Generation 2 collections has been almost completely eliminated, and the result is higher request rate and a considerable reduction in pauses due to garbage collection.

AREA	BEFORE (3.2)	AFTER (3.2.1)	DELTA %
Total request (count)	26,986	32,591	20.80%
Trace duration (seconds)	196.20	198.60	1.20%

AREA	BEFORE (3.2)	AFTER (3.2.1)	DELTA %
Request/second	137.53	164.10	19.30%
CPU Load	68.80%	68.50%	-0.40%
GC CPU Samples	124,323	17,543	-85.90%
Total allocations (count)	55,357,146	57,222,949	3.40%
Total GC Pause (samples)	15,091	8,515	-43.60%
Gen0 GC (count)	403	1,216	201.70%
Gen1 GC (count)	290	367	26.60%
Gen2 GC (count)	229	2	-99.10%
CPU / request (samples/req)	19.73	16.47	-16.50%

COLOR CODING:	CORE IMPROVEMENT	POSITIVE IMPACT ON PERFORMANCE

ASP.NET Web Pages 3.2.3 beta1

This release contains only bug fixes. You can use this query to see the list of issues fixed in this release.

What's New in ASP.NET Web Pages 3.1

by Microsoft

This topic describes what's new for ASP.NET Web Pages 3.1.

This release fixes bugs and does not introduce any new features.

Download

The runtime features are released as NuGet packages on the NuGet gallery. All the runtime packages follow the Semantic Versioning specification. The latest ASP.NET Web Pages 3.1 RTM package has the following version: "3.1.2". You can install or update these packages through NuGet. The release also includes corresponding localized packages on NuGet.

You can install or update to the released NuGet packages by using the NuGet Package Manager Console:

```
Install-Package Microsoft.AspNet.WebPages -Version 3.1.2
```

The Top Features in ASP.NET Web Pages 2

4/10/2020 • 32 minutes to read • Edit Online

by Microsoft

This article provides an overview of the top new features in the ASP.NET Web Pages 2 RC, a lightweight web programming framework that is included with Microsoft WebMatrix 2 RC.

What's included:

- Installing WebMatrix
- New and enhanced features
  - Changes for the RC release
  - Changes for the Beta release
  - Using the New and Updated Site Templates
  - Validating User Input
  - Enabling logins from Facebook and other sites using OAuth and OpenID
  - Adding Maps using the Maps Helper
  - Running Web Pages Applications Side by Side
  - Rendering Pages for Mobile Devices
- Additional Resources

> **NOTE**
>
> This topic assumes that you are using WebMatrix to work with your ASP.NET Web Pages 2 code. However, as with Web Pages 1, you can also create Web Pages 2 websites using Visual Studio, which gives you enhanced IntelliSense capabilities and debugging. To work with Web Pages in Visual Studio, you must first install Visual Studio 2010 SP1, Visual Web Developer Express 2010 SP1, or Visual Studio 11 Beta. Then install the ASP.NET MVC 4 Beta, which includes templates and tools for creating ASP.NET MVC 4 and Web Pages 2 applications in Visual Studio.

Last update: 18 June 2012

Installing WebMatrix

To install Web Pages, you can use the Microsoft Web Platform Installer, which is a free application that makes it easy to install and configure web-related technologies. You will install the WebMatrix 2 Beta, which includes Web Pages 2 Beta.

1. Browse to the installation page for the latest version of the Web Platform Installer:

   https://go.microsoft.com/fwlink/?LinkId=226883

   > **NOTE**
   >
   > If you already have WebMatrix 1 installed, this installation updates it to WebMatrix 2 Beta. You can run websites that were created using version 1 or 2 on the same computer. For more information, see the section on Running Web Pages Applications Side by Side.

2. Choose **Install Now**.

   If you use Internet Explorer, go to the next step. If you use a different browser like Mozilla Firefox or Google Chrome, you are prompted to save the *Webmatrix.exe* file to your computer. Save the file and then click it to launch the installer.

3. Run the installer and choose the **Install** button. This installs WebMatrix and Web Pages.

New and Enhanced Features

Changes for the RC Version (June 2012)

The RC version release in June 2012 has a few changes from the Beta version refresh that was released in March 2012. These changes are:

- A `Validation.AddFormError` method was added to the `Validation` helper. This is useful if you perform validation manually (for example, you validate a value that is passed in the query string) and you want to add an error message that can be displayed by the `Html.ValidationSummary` method. For more information, see the section Validating Data That Doesn't Come Directly From Users in Validating User Input in ASP.NET Web Pages (Razor) Sites.
- The functionality for bundling and minification has been removed from the core ASP.NET Web Pages 2 assemblies. As a consequence, the `Assets` helper listed later in this document is not available. Instead, you must install the ASP.NET Optimization NuGet package. For more information, see Bundling and Minifying Assets in an ASP.NET Web Pages (Razor) Site.
- Additional assemblies to support ASP.NET Web Pages 2 have been added. The only noticeable effect of this change is that you might see more assemblies in a site's *bin* folder after you create a site or deploy a site to a hosting provider.

Changes for the Beta Version (February 2012)

The Beta version released in February 2012 has only a few changes from the Beta version that was released in December 2011. These changes are:

- Razor now supports conditional attributes. In an HTML element, if you set an attribute to a value that resolves in server code to `false` or `null`, ASP.NET does not render the attribute at all. For example, imagine you have the following markup for a check box:

  ```
  <input type="checkbox"
  name="check1"
  value="check1"
  checked="@checked1" />
  ```

  If the value of `checked1` resolves to `false` or to `null`, the `checked` attribute is not rendered. This is a breaking change.

- The `Validation.GetHtml` method has been renamed to `Validation.For`. This is a breaking change; `Validation.GetHtml` will not work in the Beta release.

- You can now include the `~` operator in markup to reference the site root without using the `Href` function. (That is, the Razor parser can now find and resolve the `~` operator without requiring an explicit method call to `Href`.) The `Href` method still works, so this is not a breaking change.

  For example, if you previously had markup like this:

  ```
  <a href="@Href("~/Default.cshtml")">Home</a>
  ```

  You can now use markup like this:

```
<a href="~/Default.cshtml">Home</a>
```

- The `Scripts` helper for assets (resource) management has been replaced with the `Assets` helper, which has slightly different methods, such as the following:
  - For `Scripts.Add`, use `Assets.AddScript`
  - For `Scripts.GetScriptTags`, use `Assets.GetScripts`

    This is a breaking change; the `Scripts` class is not available in the Beta release. The code examples in this document that use asset management have been updated with this change.

Using the New and Updated Site Templates

The **Starter Site** template has been updated so that it runs on Web Pages 2 by default. It also includes the following new capabilities:

- Mobile-friendly page rendering. Through the use of CSS styles and the `@media` selector, the **Starter Site** provides improved rendering of pages on smaller screens, including mobile device screens.
- Improved membership and authentication options. You can let users log into your site using their accounts from other social networking sites, such as Twitter, Facebook, and Windows Live. For more information, see the Enabling Logins from Facebook and Other Sites using OAuth and OpenID section.
- HTML5 elements.

The new **Personal Site** template lets you create a website that contains a personal blog, a photos page, and a Twitter page. You can customize a site based on the **Personal Site** template by doing the following:

- Change the look of the site by editing the layout file (*_SiteLayout.cshtml*) and the styles file (*Site.css*).
- Install NuGet packages that add functionality to your site. For information about how to install packages, including the ASP.NET Web Helpers Library, see the tutorial about installing helpers.

To access the **Personal Site** template, choose **Templates** on the WebMatrix **Quick Start** screen.

In the **Templates** dialog box, choose the **Personal Site** template.

The landing page of the **Personal Site** template lets you follow links to set up your blog, Twitter page, and photos page.

Validating User Input

In Web Pages 1, to validate user input on submitted forms, you use the `System.Web.WebPages.Html.ModelState` class. (This is illustrated in several of the code samples in the Web Pages 1 tutorial titled Working with Data.) You can still use this approach in Web Pages 2. However, Web Pages 2 also offers improved tools for validating user input:

- New validation classes, including `System.Web.WebPages.ValidationHelper` and `System.Web.WebPages.Validator`, that let you do powerful validation tasks with a few lines of code.
- Optionally, client-side validation, which provides immediate feedback to the user instead of requiring a round trip to the server to check for validation errors. (For security reasons, validation is performed on the server even if the checks have been performed in the client beforehand.)

To use the new validation features, do the following:

In the page's code, register an element to be validated by using methods of the `Validation` helper: `Validation.RequireField`, `Validation.RequireFields` (to register multiple elements to be required), or `Validation.Add`. The `Add` method lets you specify other types of validation checks, like data-type checking, comparing entries in different fields, string-length checks, and patterns (using regular expressions). Here are some examples:

```
Validation.RequireField("text1");
Validation.RequireField("text1", "The text1 field is required");
Validation.RequireFields("text1", "text2", "text3");

Validation.Add("text1", Validation.StringLength(5));
Validation.Add("textDate", Validation.DateTime("Enter a date"));
Validation.Add("textCount", Validation.Integer("Enter a number"));
Validation.Add("textCount",
Validation.Range(1, 10, "Enter a value between 1 and 10"));
```

To display a field-specific error, call `Html.ValidationMessage` in the markup for each element being validated:

```
<input type="text" name="course"
value="@Request["course"]" />
@Html.ValidationMessage("course")
```

To display a summary (`<ul>` list) of all the errors in the page, `Html.ValidationSummary` in the markup:

```
@Html.ValidationSummary()
```

These steps are enough to implement server-side validation. If you want to add client-side validation, do the following in addition.

Add the following script file references inside the `<head>` section of a web page. The first two script references point to remote files on a content delivery network (CDN) server. The third reference points to a local script file. Production apps should implement a fallback when the CDN is unavailable. Test the fallback.

```
<script src="http://ajax.aspnetcdn.com/ajax/jQuery/jquery-1.6.2.js"></script>
<script src="http://ajax.aspnetcdn.com/ajax/jquery.validate/1.8.1/jquery.validate.min.js"></script>
<script src="~/Scripts/jquery.validate.unobtrusive.min.js"></script>
```

The easiest way to get a local copy of the *jquery.validate.unobtrusive.min.js* library is to create a new Web Pages site based on one of the site templates (such as Starter Site). The site created by the template includes *jquery.validate.unobtrusive.js* file in its Scripts folder, from which you can copy it to your site.

If your website uses a *_SiteLayout* page to control the page layout, you can include these script references in that page so that validation is available to all content pages. If you want to perform validation only on particular pages, you can use the assets manager to register the scripts on only those pages. To do this, call `Assets.AddScript(path)` in the page that you want to validate and reference each of the script files. Then add a call to `Assets.GetScripts` in the *_SiteLayout* page in order to render the registered `<script>` tags. For more information, see the section Registering Scripts with the Assets Manager.

In the markup for an individual element, call the `Validation.For` method. This method emits attributes that jQuery can hook in order to provide client-side validation. For example:

```
<input type="text" name="course"
value="@Request["course"]"
@Validation.For("course")
/>
@Html.ValidationMessage("course")
```

The following example shows a page that validates user input on a form. To run and test this validation code, do this:

1. Create a new web site using one of the WebMatrix 2 site templates that includes a *Scripts* folder, such as the **Starter Site** template.
2. In the new site, create a new *.cshtml* page, and replace the contents of the page with the following code.
3. Run the page in a browser. Enter valid and invalid values to see the effects on validation. For example, leave a required field blank or enter a letter in the **Credits** field.

```
@{
// Specify what fields users must fill in.
Validation.RequireFields("course", "professorname", "credits");
// Add validation criteria.  Here, require that input to Credits is an integer.
Validation.Add("credits", Validator.Integer());

if (IsPost)  {
// Wrap the postback code with a validation check.
if (Validation.IsValid()) {
    var course = Request["course"];
    var professorName = Request["professorname"];
    var credits = Request["credits"];
    // Display valid input values.
    <text>
        You entered: <br />
        Class: @course <br />
        Professor: @professorName <br />
        Credits: @credits <br />
    </text>
}
}
}
<!DOCTYPE html>
<html lang="en">
<head>
<meta charset="utf-8" />
<title>Testing Validation in ASP.NET Web Pages version 2</title>
<script src="http://ajax.aspnetcdn.com/ajax/jQuery/jquery-1.6.2.js"></script>
<script  src="http://ajax.aspnetcdn.com/ajax/jquery.validate/1.8.1/jquery.validate.min.js"></script>
<script src="@Href("~/Scripts/jquery.validate.unobtrusive.min.js")"></script>
</head>
<body>
<form method="post" action="">
<!-- Display a summary message about any validation issues. -->
@Html.ValidationSummary()
<fieldset>
  <legend>Add Class</legend>
<div>
  <label for="Course">Class:</label>
  <!-- Validation.For("course") adds validation attributes to the input element. -->
  <input type="text" name="Course" value="@Request["course"]"  @Validation.For("course") />

  <!-- Display a field-specific message about validation issues. -->
  @Html.ValidationMessage("course")
</div>

<div>
  <label for="ProfessorName">Professor:</label>
  <input type="text" name="ProfessorName" value="@Request["professorname"]"
```

```
      @Validation.For("professorname") />
  @Html.ValidationMessage("professorname")
</div>

<div>
  <label for="Credits">Credits:</label>
  <input type="text" name="Credits" value="@Request["credits"]" @Validation.For("credits") />
  @Html.ValidationMessage("credits")
</div>

<div>
  <label> </label>
  <input type="submit" value="Submit" class="submit" />
</div>
  </fieldset>
</form>
</body>
</html>
```

Here is the page when a user submits valid input:

Here is the page when a user submits it with a required field left empty:

Here is the page when a user submits it with something other than an integer in the **Credits** field:

For more information, see the following blog posts:

- Updated validation in Web Pages v2 Basics of adding validation using the `Validation` helper (server-side only)
- Updated validation in Web Pages v2, Part 2 Adding client-side validation.
- Updated validation in Web Pages v2, Part 3 Formatting validation errors.

Registering Scripts Using the Assets Manager

The assets manager is a new feature that you can use in server code to register and render client scripts. This feature is helpful when you are working with code from multiple files (such as layout pages, content pages, helpers, etc.) that are combined into a single page at run time. The assets manager coordinates the source files to make sure that script files are referenced correctly and efficiently on the rendered page, regardless of which code files they are called from or how many times they are called. The assets manager also renders `<script>` tags in the right place so that the page can load quickly (without downloading scripts while rendering) and to avoid errors that can occur if scripts are called before rendering is complete.

For example, suppose that you create a custom helper that calls a JavaScript file, and you call this helper at three different places in your content page code. If you don't use the assets manager to register the script calls in the helper, three different `<script>` tags that all point to the same script file will appear in your rendered page. Plus, depending on where the `<script>` tags are inserted in the rendered page, errors may occur if the script tries to access certain page elements before the page fully loads. If you use the assets manager to register the script, you avoid these problems.

You can register a script with the assets manager by doing this:

- In the code that needs to reference the script, call the `Assets.AddScript` method.
- In a *_SiteLayout* page, call the `Assets.GetScripts` method to render the `<script>` tags.

> **NOTE**
> Put calls to `Assets.GetScripts` as the very last item in the `<body>` element of the *_SiteLayout* page. This helps the page load faster and can help avoid script errors.

The following example shows how the assets manager works. The code contains the following items:

- A custom helper named `MakeNote`. This helper renders a string inside a box by wrapping a `div` element

around it that's styled with a border and by adding "Note:" to it. The helper also calls a JavaScript file that adds run-time behavior to the note. Rather than reference the script with a `<script>` tag, the helper registers the script by calling `Assets.AddScript` .

- A JavaScript file. This is the file that's called by the helper, and it temporarily increases the font size of note items during a `mouseover` event.
- A content page, which references the *_SiteLayout* page, renders some content in the body, and then calls the `MakeNote` helper.
- A *_SiteLayout* page. This page provides a common header and a page layout structure. It also includes a call to `Assets.GetScripts`, which is how the assets manager renders script calls in a page.

To run the sample:

1. Create an empty Web Pages 2 website. You can use the WebMatrix **Empty Site** template for this.
2. Create a folder named *Scripts* in the site.
3. In the *Scripts* folder, create a file named *Test.js*, copy the *Test.js* content into it from the example, and save the file..
4. Create a folder named *App_Code* in the site.
5. In the *App_Code* folder, create a file named *Helpers.cshtml*, copy the example code into it, and save it in a folder named *App_Code* in the root folder.
6. In the site's root folder, create a file named *_SiteLayout.cshtml,* copy the example into it, and save the file.
7. In the site root, create a file named *ContentPage.cshtml*, add the example code, and save it.
8. Run *ContentPage* in a browser. The string you passed to the `MakeNote` helper is rendered as a boxed note.
9. Pass the mouse pointer over the note. The script temporarily increases the font size of the note.
10. View the source of the rendered page. Because of where you placed the call to `Assets.GetScripts`, the rendered `<script>` tag that calls *Test.js* is the very last item in the body of the page.

Test.js

```
function UpdateNoteStyle(id) {
var theNote = document.getElementById(id);
theNote.style.fontSize = "150%";
}
function ReturnNoteStyle(id) {
var theNote = document.getElementById(id);
theNote.style.fontSize = "inherit";
}
```

Helpers.cshtml

```
@helper MakeNote(string content, string noteid) {
Assets.AddScript("~/Scripts/Test.js");

<div id="@noteid" style="border: 1px solid black; width: 90%; padding: 5px; margin-left: 15px;"
 onmouseover="UpdateNoteStyle('@noteid')" onmouseout="ReturnNoteStyle('@noteid')">
  <p>
  <strong>Note</strong>   @content
   </p>
</div>
}
```

_SiteLayout.cshtml

```
<!DOCTYPE html>

<html lang="en">
<head>
<meta charset="utf-8" />

```

The following screenshot shows *ContentPage.cshtml* in a browser when you hold the mouse pointer over the note:

Enabling Logins from Facebook and Other Sites Using OAuth and OpenID

Web Pages 2 provides enhanced options for membership and authentication. The main enhancement is that there are new OAuth and OpenID providers. Using these providers, you can let users log into your site using their existing credentials from Facebook, Twitter, Windows Live, Google, and Yahoo. For example, to log in using a Facebook account, users can just choose a Facebook icon, which redirects them to the Facebook login page where they enter their user information. They can then associate the Facebook login with their account on your site. A

related enhancement to the Web Pages membership features is that users can associate multiple logins (including logins from social networking sites) with a single account on your website.

This image shows the Login page from the **Starter Site** template, where a user can choose a Facebook, Twitter, or Windows Live icon to enable logging in with an external account:

You can enable OAuth and OpenID membership using just a few lines of code. The methods and properties you use to work with the OAuth and OpenID providers are in the `WebMatrix.Security.OAuthWebSecurity` class.

However, instead of using code to enable logins from other sites, a recommended way to get started with the new providers is to use the new **Starter Site** template that is included with WebMatrix 2 Beta. The **Starter Site** template includes a full membership infrastructure, complete with a login page, a membership database, and all the code you need to let users log into your site using either local credentials or those from another site.

How to Enable Logins using the OAuth and OpenID Providers

This section provides an example of how to let users log in from external sites (Facebook, Twitter, Windows Live, Google, or Yahoo) to a site that's based on the **Starter Site** template. After creating a starter site, you do this (details follow):

- For the sites that use an OAuth provider (Facebook, Twitter, and Windows Live), create an application on the external site. This gives you application keys that you'll need in order to invoke the login feature for those sites. For sites that use an OpenID provider (Google, Yahoo), you do not have to create an application. For all of these sites, you must have an account in order to log in and to create developer applications.

  > **NOTE**
  > Windows Live applications only accept a live URL for a working website, so you cannot use a local website URL for testing logins.

- Edit a few files in your website in order to specify the appropriate authentication provider and to submit a login to the site you want to use.

To enable Google and Yahoo logins:

1. In your website, edit the *_AppStart.cshtml* page and add the following two lines of code in the Razor code block after the call to the `WebSecurity.InitializeDatabaseConnection` method. This code enables both the Google and Yahoo OpenID providers.

```
OAuthWebSecurity.RegisterOpenIDClient(BuiltInOpenIDClient.Google);
OAuthWebSecurity.RegisterOpenIDClient(BuiltInOpenIDClient.Yahoo);
```

2. In the *~/Account/Login.cshtml* page, remove the comments from the following `<fieldset>` block of markup near the end of the page. To uncomment the code, remove the `@*` characters that precede and follow the `<fieldset>` block. The resulting code block looks like this:

```
<fieldset>
<legend>Log in using another service</legend>
<input type="submit" name="provider" id="facebook" value="Facebook" title="Log in using your Facebook
account." />
<input type="submit" name="provider" id="twitter" value="Twitter" title="Log in using your Twitter
account." />
<input type="submit" name="provider" id="windowsLive" value="WindowsLive" title="Log in using your
Windows Live account." />
</fieldset>
```

3. Add an `<input>` element for the Google or Yahoo provider to the `<fieldset>` group in the *~/Account/Login.cshtml* page. The updated `<fieldset>` group with `<input>` elements for both Google and Yahoo looks like the following example:

```
<fieldset>
<legend>Log in using another service</legend>
<input type="submit" name="provider" id="facebook" value="Facebook" title="Log in using your Facebook
account." />
<input type="submit" name="provider" id="twitter" value="Twitter" title="Log in using your Twitter
account." />
<input type="submit" name="provider" id="windowsLive" value="WindowsLive" title="Log in using your
Windows Live account." />
<input type="submit" name="provider" id="yahoo" value="Yahoo" title="Log in using your Yahoo account."
/>
<input type="submit" name="provider" id="google" value="Google" title="Log in using your Google
account." />
</fieldset>
```

4. In the *~/Account/AssociateServiceAccount.cshtml* page, add `<input>` elements for Google or Yahoo to the `<fieldset>` group near the end of the file. You can copy the same `<input>` elements that you just added to the `<fieldset>` section in the *~/Account/Login.cshtml* page.

   The *~/Account/AssociateServiceAccount.cshtml* page in the Starter Site template can be used if you want to create a page on which users can associate multiple logins from other sites with a single account on your website.

Now you can test Google and Yahoo logins.

1. Run the *default.cshtml* page of your site and choose the **Log in** button.

2. On the *Login* page, in the **Use another service to log in** section, choose either the **Google** or **Yahoo** submit button. This example uses the Google login.

   The web page redirects the request to the Google login page.

3. Enter credentials for an existing Google account.

4. If Google asks you whether you want to allow Localhost to use information from the account, click **Allow**.

   The code uses the Google token to authenticate the user, and then returns to this page on your website. This page lets users associate their Google login with an existing account on your website, or they can register a new account on your site to associate the external login with.

5. Choose the **Associate** button. The browser returns to your application's home page.

To enable Facebook logins:

1. Go to the Facebook developers site (log in if you're not already logged in).

2. Choose the **Create New App** button, and then follow the prompts to name and create the new application.

3. In the section **Select how your app will integrate with Facebook**, choose the **Website** section.

4. Fill in the **Site URL** field with the URL of your site (for example, `http://www.example.com`). The **Domain** field is optional; you can use this to provide authentication for an entire domain (such as *example.com*).

> **NOTE**
> If you are running a site on your local computer with a URL like `http://localhost:12345` (where the number is a local port number), you can add this value to the **Site URL** field for testing your site. However, any time the port number of your local site changes, you will need to update the **Site URL** field of your application.

5. Choose the **Save Changes** button.

6. Choose the **Apps** tab again, and then view the start page for your application.

7. Copy the **App ID** and **App Secret** values for your application and paste them into a temporary text file. You will pass these values to the Facebook provider in your website code.

8. Exit the Facebook developer site.

Now you make changes to two pages in your website so that users will able to log into the site using their Facebook accounts.

1. In your website, edit the *_AppStart.cshtml* page and uncomment the code for the Facebook OAuth provider. The uncommented code block looks like the following:

```
OAuthWebSecurity.RegisterOAuthClient(
BuiltInOAuthClient.Facebook,
consumerKey: "",   // for Facebook, consumerKey is called AppID in the SDK
consumerSecret: "");
```

2. Copy the **App ID** value from the Facebook application as the value of the `consumerKey` parameter (inside the quotation marks).

3. Copy **App Secret** value from the Facebook application as the `consumerSecret` parameter value.

4. Save and close the file.

5. Edit the *~/Account/Login.cshtml* page and remove the comments from the `<fieldset>` block near the end of the page. To uncomment the code, remove the `@*` characters that precede and follow the `<fieldset>` block. The code block with comments removed looks like the following:

```
<fieldset>
<legend>Log in using another service</legend>
<input type="submit" name="provider" id="facebook" value="Facebook" title="Log in using your Facebook
account." />
<input type="submit" name="provider" id="twitter" value="Twitter" title="Log in using your Twitter
account." />
<input type="submit" name="provider" id="windowsLive" value="WindowsLive" title="Log in using your
Windows Live account." />
</fieldset>
```

6. Save and close the file.

Now you can test the Facebook login.

1. Run the site's *default.cshtml* page and choose the **Login** button.

2. On the *Login* page, in the **Use another service to log in** section, choose the **Facebook** icon.

   The web page redirects the request to the Facebook login page.

3. Log into a Facebook account.

   The code uses the Facebook token to authenticate you and then returns to a page where you can associate your Facebook login with your site's login. Your user name or email address is filled into the **Email** field on the form.

4. Choose the **Associate** button.

   The browser returns to the home page and you are logged in.

To enable Twitter logins:

1. Browse to the Twitter developers site.
2. Choose the **Create an App** link and then log into the site.
3. On the **Create an Application** form, fill in the **Name** and **Description** fields.
4. In the **WebSite** field, enter the URL of your site (for example, `http://www.example.com`).

> **NOTE**
> If you're testing your site locally (using a URL like `http://localhost:12345`), Twitter might not accept the URL. However, you might be able to use the local loopback IP address (for example `http://127.0.0.1:12345`). This simplifies the process of testing your application locally. However, every time the port number of your local site changes, you'll need to update the **WebSite** field of your application.

5. In the **Callback URL** field, enter a URL for the page in your website that you want users to return to after logging into Twitter. For example, to send users to the home page of the Starter Site (which will recognize their logged-in status), enter the same URL that you entered in the **WebSite** field.
6. Accept the terms and choose the **Create your Twitter application** button.
7. On the **My Applications** landing page, choose the application you created.
8. On the **Details** tab, scroll to the bottom and choose the **Create My Access Token** button.
9. On the **Details** tab, copy the **Consumer Key** and **Consumer Secret** values for your application and paste them into a temporary text file. You'll pass these values to the Twitter provider in your website code.
10. Exit the Twitter site.

Now you make changes to two pages in your website so that users will be able to log into the site using their Twitter accounts.

1. In your website, edit the *_AppStart.cshtml* page and uncomment the code for the Twitter OAuth provider. The uncommented code block looks like this:

```
OAuthWebSecurity.RegisterOAuthClient(
BuiltInOAuthClient.Twitter,
consumerKey: "",
consumerSecret: "");
```

2. Copy the **Consumer Key** value from the Twitter application as the value of the `consumerKey` parameter (inside the quotation marks).

3. Copy the **Consumer Secret** value from the Twitter application as the value of the `consumerSecret` parameter.

4. Save and close the file.

5. Edit the *~/Account/Login.cshtml* page and remove the comments from the `<fieldset>` block near the end of the page. To uncomment the code, remove the `@*` characters that precede and follow the `<fieldset>` block. The code block with comments removed looks like the following:

```
<fieldset>
<legend>Log in using another service</legend>
<input type="submit" name="provider" id="facebook" value="Facebook" title="Log in using your Facebook
account." />
<input type="submit" name="provider" id="twitter" value="Twitter" title="Log in using your Twitter
account." />
<input type="submit" name="provider" id="windowsLive" value="WindowsLive" title="Log in using your
Windows Live account." />
</fieldset>
```

6. Save and close the file.

Now you can test the Twitter login.

1. Run the *default.cshtml* page of your site and choose the **Login** button.

2. On the *Login* page, in the **Use another service to log in** section, choose the **Twitter** icon.

   The web page redirects the request to a Twitter login page for the application you created.

3. Log into a Twitter account.

4. The code uses the Twitter token to authenticate the user and then returns you to a page where you can associate your login with your website account. Your name or email address is filled into the **Email** field on the form.

5. Choose the **Associate** button.

   The browser returns to the home page and you are logged in.

Adding Maps Using the Maps Helper

Web Pages 2 includes additions to the ASP.NET Web Helpers Library, which is a package of add-ins for a Web Pages site. One of these is a mapping component provided by the `Microsoft.Web.Helpers.Maps` class. You can use the `Maps` class to generate maps based either on an address or on a set of longitude and latitude coordinates. The `Maps` class lets you call directly into popular map engines including Bing, Google, MapQuest, and Yahoo.

To use the new `Maps` class in your website, you must first install the version 2 of the Web Helpers Library. To do this, go to the instructions for installing the currently released version of the ASP.NET Web Helpers Library and install version 2.

The steps for adding mapping to a page are the same regardless of which of the map engines you call. You just add a JavaScript file reference to your mapping page and then add a call that renders the `<script>` tags on your page. Then on your mapping page, call the map engine you want to use.

The following example shows how to create a page that renders a map based on an address, and another page that renders a map based on longitude and latitude coordinates. The address mapping example uses Google Maps, and the coordinate mapping example uses Bing Maps. Note the following elements in the code:

- The call to `Assets.AddScript` at the top of the two mapping pages. This method adds a reference to the *jquery-1.6.2.min.js* file that is included with the **Starter Site** template and that's required by the `Maps` class.
- The call to the `Assets.GetScripts` method in the layout file. This method renders the `<script>` tag on the two mapping pages.
- The call to the `@Maps.GetGoogleHtml` and the `@Maps.GetBingHtml` methods in the mapping pages. To map an address, you must pass an address string. To map coordinates, you must pass longitude and latitude coordinates. For the Bing Maps engine, you must also pass a key (which you get for free by signing up at the Bing Maps Developers site). The methods for the other map engines work in a similar way (`@Maps.GetYahooHtml` , `@Maps.GetMapQuestHtml`).

To create mapping pages:

1. Create a website based on the **Starter Site** template.
2. Create a file named *MapAddress.cshtml* in the root of the site. This page will generate a map based on an address that you pass to it.
3. Copy the following code into the file, overwriting the existing content.

```
@{
Layout = "~/_MapLayout.cshtml";
Assets.AddScript("~/Scripts/jquery-1.6.2.min.js");
}

<div id="navigation">
<h3>Map an Address:</h3>
<form method="post" action="" id="coordinates" style="width: 320px">
<fieldset>
  <div>
    <label for="address">Address:</label>
    <input style="width: 300px" type="text"  name="address"  value="@Request["address"]"/>
    <input type="submit" value="Map It!" />
   </div>
</fieldset>
</form>
</div>
<div id="content">
@if(IsPost) {
var theAddress = Request["address"];
@Maps.GetGoogleHtml(theAddress,
    width: "800",
    height: "800")
}
</div>
```

4. Create a file named *_MapLayout.cshtml* in the root of the site. This page will be the layout page for the two mapping pages.
5. Copy the following code into the file, overwriting the existing content.

```
<!DOCTYPE html>

<html lang="en">
<head>
<meta charset="utf-8" />

<title></title>
<style type="text/css">
    #navigation {
        position: absolute;
        top: 1em;
        left: 3em;
        width: 18em;
    }
    #content {
        margin-top: 10em;
        margin-left: 3em;
    }
</style>
</head>
<body>
  @RenderBody()

  @*
Call the Assets helper to render tags for the Maps helper. For
releases after Web Pages 2 Beta, call Assets.GetScripts().
  *@
  @Assets.GetScripts()
</body>
</html>
```

6. Create a file named *MapCoordinates.cshtml* in the root of the site. This page will generate a map based on a set of coordinates that you pass to it.

7. Copy the following code into the file, overwriting the existing content.

```
@{
Layout = "~/_MapLayout.cshtml";
Assets.AddScript("~/Scripts/jquery-1.6.2.min.js");
}

<div id="navigation">
<h3>Map a set of coordinates:</h3>
<form method="post" action="" id="coordinates">
<fieldset>
<div>
    <label for="latitude">Latitude:   </label>
    <input type="text"  name="latitude" value="@Request["latitude"]"/>
</div>
<div>
    <label for="longitude">Longitude:</label>
    <input type="text" name="longitude" value="@Request["longitude"]"/>
</div>
<div>
    <input type="submit" value="Map It!" />
</div>
</fieldset>
</form>
</div>
<div id="content">
@if(IsPost) {
var theLatitude = Request["latitude"];
var theLongitude = Request["longitude"];
@Maps.GetBingHtml("Ag6C5Ci9VUGz9AIhQyJ7YNwGraanqwy5-V3LK1qGDpdEVPV-MUPBryG18ELoC6g6",
    "",
    theLatitude,
    theLongitude,
    width: "800",
    height: "800")
}
</div>
```

To test your mapping pages:

1. Run the page *MapAddress.cshtml* file.
2. Enter a full address string including a street address, state or province, and postal code, and then choose the **Map It** button. The page renders a map from Google Maps:

3. Find a set of latitude and longitude coordinates for a specific location.

4. Run the page *MapCoordinates.cshtml*. Enter the coordinates and then choose the **Map It** button. The page renders a map from Bing Maps:

Running Web Pages Applications Side by Side

Web Pages 2 adds the ability to run applications side by side. This lets you continue to run your Web Pages 1 applications, build new Web Pages 2 applications, and run all of them on the same computer.

Here are some things to remember when you install the Web Pages 2 Beta with WebMatrix:

- By default, existing Web Pages applications will run as version 2 applications on your computer. (The assemblies for version 2 are installed in the GAC and will be used automatically.)
- If you want to run a site using Web Pages version 1 (instead of the default, as in the previous point), you can configure the site to do that. If your site doesn't already have a *web.config* file in the root of the site, create a new one and copy the following XML into it, overwriting the existing content. If the site already contains a *web.config* file, add an `<appSettings>` element like the following one to the `<configuration>` section.

  ```
  <?xml version="1.0"?>
  <configuration>
  <appSettings>
  <add key="webPages:Version" value="1.0"/>
  </appSettings>
  </configuration>
  ```

  `- If you do not specify a version in the *web.config* file, a site is deployed as a version 2 site. (The version 2 assemblies are copied to the *bin* folder in the deployed site.)
- New applications that you create using the site templates in Web Matrix version 2 Beta include the Web

Pages version 2 assemblies in the site's *bin* folder.

In general, you can always control which version of Web Pages to use with your site by using NuGet to install the appropriate assemblies into the site's *bin* folder. To find packages, visit NuGet.org.

Rendering Pages for Mobile Devices

Web Pages 2 lets you create custom displays for rendering content on mobile or other devices.

The `System.Web.WebPages` namespace contains the following classes that let you work with display modes: `DefaultDisplayMode`, `DisplayInfo`, and `DisplayModes`. You can use these classes directly and write code that renders the right output for specific devices.

Alternatively, you can create device-specific pages by using a file-naming pattern like this: *FileName.Mobile.cshtml*. For example, you can create two versions of a page, one named *MyFile.cshtml* and one named *MyFile.Mobile.cshtml*. At run time, when a mobile device requests *MyFile.cshtml*, Web Pages renders the content from *MyFile.Mobile.cshtml*. Otherwise, *MyFile.cshtml* is rendered.

The following example shows how to enable mobile rendering by adding a content page for mobile devices. *Page1.cshtml* contains content plus a navigation sidebar. *Page1.Mobile.cshtml* contains the same content, but omits the sidebar.

To build and run the code sample:

1. In a Web Pages site, create a file named *Page1.cshtml* and copy the *Page1.cshtml* content into it from the example.
2. Create a file named *Page1.Mobile.cshtml* and copy the *Page1.Mobile.cshtml* content into it from the example. Notice that the mobile version of the page omits the navigation section for better rendering on a smaller screen.
3. Run a desktop browser and browse to *Page1.cshtml*.
4. Run a mobile browser (or a mobile device emulator) and browse to *Page1.cshtml*. Notice that this time Web Pages renders the mobile version of the page.

> **NOTE**
>
> To test mobile pages, you can use a mobile device simulator that runs on a desktop computer. This tool lets you test web pages as they would look on mobile devices (that is, typically with a much smaller display area). One example of a simulator is the User Agent Switcher add-on for Mozilla Firefox, which lets you emulate various mobile browsers from a desktop version of Firefox.

Page1.cshtml

```
<!DOCTYPE html>

<html lang="en">
<head>
<meta charset="utf-8" />
<title></title>
<style type="text/css">
    #navigation {
        position: absolute;
        top: 0;
        left: 0;
        width: 10em;
    }
    #content {
    margin-left: 13em;
        margin-right: 10em;
    }
</style>
</head>
<body>
<div id="navigation">
    <h3>Related Sites</h3>
    <ul>
        <li><a href="http://www.adventure-works.com/">Adventure Works</a></li>
        <li><a href="http://www.contoso.com/">Contoso, Ltd</a></li>
        <li><a href="http://www.treyresearch.net/">Trey Research</a></li>
    </ul>
</div>
<div id="content">

ASP.NET Web Pages 2 Developer Preview ReadMe

14 September 2011

Contents

Installation Notes

To install Web Pages 2 Developer Preview, you have these options:

- Install WebMatrix 2 Beta using the Web Platform Installer. WebMatrix is a set of free web development tools that includes ASP.NET Web Pages. For more information, see the installation section in The Top Features in ASP.NET Web Pages 2 Developer Preview.
- Install Web Pages 2 Developer Preview directly using the download link. Use this approach if you want to create Web Pages applications using a text editor such as Notepad. In order to run Web Pages 2 applications, you must have IIS Express 7.5. (This is included automatically with WebMatrix.) For tips on how to test a Web Pages page using IIS Express, see the sidebar "Creating and Testing ASP.NET Pages Using Your Own Text Editor" in Getting Started with WebMatrix and ASP.NET Web Pages.

ASP.NET Web Pages 2 Developer Preview can be installed and can run side-by-side with ASP.NET Web Pages 1. For details, see the section "Running Web Pages Applications Side-by-Side" in The Top Features in Web Pages 2 Developer Preview.

Documentation

Tutorials and other information about ASP.NET Web Pages are available on the Web Pages page of the ASP.NET website (https://www.asp.net/web-pages/). For information about new features and enhancements in Web Pages 2, see The Top Features in Web Pages 2 Developer Preview.

Support

This is a preview release and is not officially supported. If you have questions about working with this release, post them to the ASP.NET Web Pages forum (https://forums.asp.net/1224.aspx/1?WebMatrix), where members of the ASP.NET community are frequently able to provide informal support.

Software Requirements

ASP.NET Web Pages 2 requires the .NET Framework 4. It also works with the .NET Framework 4.5 Developer Preview release.

Fixes, Known Issues, and Breaking Changes

- **Is* methods (for example, IsDateTime) now return correct values for all cultures.** Some methods like *IsDateTime* previously returned *false* when they should have returned *true* because they were previously performing culture-specific checks. These methods have been fixed to now take culture into account. This is a breaking change; if your application relies on the old behavior, it will break.
- **The behavior of the Href method has changed.** Previously, calling Href("~/SomeFile") would return a URL relative to the currently executing file. Now Href("~/SomeFile") always returns an absolute path from the root of the application. For most cases, this behavior won't make a difference in the return value. This change was made to fix certain Ajax scenarios. For example, consider the following example code:

```
/Folder/File
@Href("~/Images/Logo.jpg")
```

This code previously would resolve to Images/Logo.jpg, which would be incorrect for an Ajax request to that page. It will now resolve to the root of the (/MySite/Images/Logo.jpg).

- **The HttpContext.RedirectLocal method has changed**. This method now accepts only URLs that are relative to the current application. Fully qualified URLs are rejected.
- **The ModelState.IsValid method now requires you to call Validate first**. If you are converting your application to use the new input validation methods and are calling the *ModelState.IsValid* method, you must now call *Validation.Validate* beforehand. For example, you must now follow this pattern:

```
Validation.RequireField("MyField");
if (IsPost) {
    Validation.Validate();
    if (ModelState.IsValid) {
        // do something
    }
}
```

However, we recommend that if you use the new input validation methods, don't use *ModelState.IsValid*. Instead, structure your code like this:

```
Validation.RequireField("MyField");
if (IsPost) {
    if (Validation.IsValid()) {
        // do something
    }
}
```

- **On Internet Explorer 7 and Internet Explorer 8, client-side validation does not work**. Client-side validation does not work due to incompatibilities with jQuery 1.6.2, which is included with the default project template. (Server-side validation works.).

Running Different Versions of ASP.NET Web Pages (Razor) Side by Side

2/20/2020 • 2 minutes to read • Edit Online

by Tom FitzMacken

This article explains how to run ASP.NET Web Pages (Razor) websites on the same computer or server when the websites are configured to use different versions of ASP.NET Web Pages.

What you'll learn:

- What the default behavior is in ASP.NET when you have sites built with ASP.NET Web Pages.
- How to configure a new site to run with an older version of ASP.NET Web Pages.

This is the ASP.NET feature introduced in the article:

- The `webPages:Version` configuration setting.

Software versions

- ASP.NET Web Pages (Razor) 3

This tutorial also works with ASP.NET Web Pages 2 and ASP.NET Web Pages 1.0.

ASP.NET Web Pages supports the ability to run websites side by side. This lets you continue to run your older ASP.NET Web Pages applications, build new ASP.NET Web Pages applications, and run all of them on the same computer.

Here are some things to remember when you install the Web Pages with WebMatrix:

- By default, existing Web Pages applications will run as the latest version on your computer. (The assemblies are installed in the global assembly cache (GAC) and are used automatically.)

- If you want to run a site using a different version of ASP.NET Web Pages, you can configure the site to do that. If your site doesn't already have a *web.config* file in the root of the site, create a new one and copy the following XML into it, overwriting the existing content. If the site already contains a *web.config* file, add an `<appSettings>` element like the following one to the `<configuration>` section.

  ```
  <?xml version="1.0"?>
  <configuration>
    <appSettings>
      <add key="webPages:Version" value="1.0"/>
    </appSettings>
  </configuration>
  ```

  `- If you do not specify a version in the *web.config* file, a site is deployed as the latest version. (The assemblies are copied to the *bin* folder in the deployed site.)

- New applications that you create using the site templates in Web Matrix include the Web Pages version assemblies in the site's *bin* folder.

In general, you can always control which version of Web Pages to use with your site by using NuGet to install the

appropriate assemblies into the site's *bin* folder. To find packages, visit NuGet.org.

- Changes and Issues
  - WebMatrix 1.0 Installation
  - ASP.NET Web Pages
  - WebMatrix
  - IIS Express
  - SQL Server Compact
  - Installing Applications
  - Publishing Applications
- For More Information

Overview

Microsoft WebMatrix 1.0 is a free web development stack that installs in minutes. It integrates a web server with database and programming frameworks to create a single, integrated experience. You can use WebMatrix to streamline the way you code, test, and publish your own ASP.NET or PHP website, or you can use WebMatrix to start a new website using popular open-source apps like DotNetNuke, Umbraco, WordPress, or Joomla. WebMatrix uses the same powerful web server, database engine, and frameworks environment that will run your website on the internet, which makes the transition from development to production smooth and seamless.

Installation

To install WebMatrix 1.0, you must first install the Microsoft Web Platform Installer 3.0. After you've installed the Web Platform Installer, you can use it to install WebMatrix.

If you have problems during installation, refer to Troubleshooting Problems with Microsoft Web Platform Installer.

How to Publish Applications

See Step-by-Step Instructions for Publishing Applications

Changes and Issues

WebMatrix 1.0 Installation Issues

Issue: WebMatrix 1.0 is available only on platforms that support Microsoft .NET Framework 4

The .NET Framework version 4 is required for WebMatrix. In certain cases, the WebMatrix 1.0 installer will let you try to install on a platform that is not part of the supported configuration set. In particular, Windows Vista without the SP1 update will let you begin the installation of WebMatrix, but the .NET Framework 4 component will fail and block your installation.

Workaround

Install on a supported platform, which includes:

- Windows 7
- Windows Server 2008
- Windows Server 2008 R2
- Windows Vista SP1 or later
- Windows XP SP3
- Windows Server 2003 SP2

Issue: Cannot install WebMatrix 1.0 if Microsoft Visual Studio 2008 is installed without Microsoft Visual Studio 2008 SP1

Workaround

Install Microsoft Visual Studio 2008 SP1 from the Microsoft Download Center.

Issue: Some assemblies for SQL Server Compact 4.0 are not installed in the GAC

The managed assemblies for SQL Server Compact 4.0 are not placed in the global assembly cache (GAC) when you install SQL Server Compact 4.0 on a 64-bit computer and the computer has only the .NET Framework 3.5 SP1 Client Profile installed. The managed assemblies that are not installed in the GAC are:

- *System.Data.SqlServerCe.dll* (ADO.NET provider)
- *System.Data.SqlServerCe.Entity.dll* (ADO.NET Entity Framework)

Workaround

Uninstall SQL Server Compact 4.0. Download and install the full version of .NET Framework 3.5 SP1 from the following location:

Microsoft .NET Framework 3.5 Service pack 1 (Full Package)

Then reinstall SQL Server Compact 4.0.

Issue: Cannot uninstall SQL Server Compact using the command line

Uninstallation of SQL Server Compact using command-line options does not work in this release.

Workaround

Use *Programs and Features* in the Windows Control Panel to uninstall Microsoft SQL Server Compact 4.0.

ASP.NET Web Pages

This section of the document describes new features, changes, and known issues with the 1.0 release of ASP.NET Web Pages with Razor syntax.

- New features
- Changes
- Issues

New Features

New: Configuration setting added to disable the package manager

A new `asp:AdminManagerEnabled` key is available for the `<appSettings>` element in the *web.config* file, which lets you completely disable the package manager. The default value for this element is true, meaning that if it is not included in the *web.config* file, the package manager is enabled. To disable the package manager, add the following element to the *web.config* file in the root of the website:

```
<configuration>
  <appSettings>
    <add key="asp:AdminManagerEnabled" value="false"/>
  </appSettings>
</configuration>
```

Changes

Change: "webPages:AdminFolderVirtualPath" key renamed to "asp:AdminFolderVirtualPath"

The `webPages:AdminFolderVirtualPath` key that can be added to the *web.config* file to specify the location of the package manager has been renamed to use the `asp:` namespace instead of the `webPages` namespace. If you have used this element, you must rename it in the configuration file.

Known Issues

Issue: Passwords for membership users no longer recognized

The algorithm for creating and storing membership (login) passwords has been changed to be more secure. As a result, the passwords stored for members (users) created in Beta versions of ASP.NET Razor will not be recognized.

Workaround If the site has not yet been put into production, remove the user records from the membership database. If database is live, programmatically regenerate existing passwords in the membership database.

Issue: Unexpected behavior when using a custom user table for membership

To initialize the membership provider for an ASP.NET Razor website, you call the `WebSecurity.InitializeDatabaseConnection` method. (In WebMatrix, the Starter Site template includes a call to this method in the *_AppStart.cshtml* file.) If the `autoCreateTables` parameter of this method is set to true (by default, it is set to true in the Starter Site template), and if an unrecognized table name is passed to the method (the second parameter), the method does not throw an error. Instead, it automatically creates the table.

This can be a problem if you intend to use a custom user table for membership but pass the wrong table name to the `WebSecurity.InitializeDatabaseConnection` method. Because the method does not by default raise an error if the table you specify does not exist, and because it instead creates a new table, the application can appear to be working. However, application code that relies on your custom user table (and on fields in it) can eventually fail with unexpected errors.

Workaround

Make sure that the name passed in the `InitializeDatabaseConnection` method matches the user profile table in the membership database, or make sure that the `autoCreateTables` parameter is set to false.

Issue: Error message "The Admin Module requires access to ~/App_Data"

Under some circumstances, trying to create users or otherwise work with the ASP.NET membership system can cause the page to display the error *The Admin Module requires access to ~/App_Data*. This occurs if the account that IIS or IIS Express is running under does not have permissions to create and write to the *App_Data* folder under the website root.

Workaround Manually create an *App_Data* folder for the website. Then make sure that the Windows account that the application runs under (typically NETWORK SERVICE) has read/write permissions for root folders of the application and for subfolders such as App_Data. More detailed information is available in the KnowledgeBase article Problems with SQL Server Express user instancing and ASP.net Web Application Projects.

Issue: "Failed to generate a user instance of SQL Server" error

If a WebMatrix Web application uses SQL Server Express and is running IIS 7.5 on Windows 7 or Windows Server 2008 R2, you might see an error that indicates that SQL Server cannot retrieve the user's local application path at run time.

Workaround Make sure that the Windows account that the application runs under (typically NETWORK SERVICE) has read/write permissions for root folders of the application and for subfolders such as *App_Data*. More detailed information is available in the KnowledgeBase article Problems with SQL Server Express user instancing and ASP.net Web Application Projects.

Issue: Files that contains package-manager resources or package-manager passwords are servable under IIS 6.0 and earlier

If you deploy an ASP.NET Web Pages (Razor) application that was built using the RC2 release, and if the application contains a *password.txt* or *packagesources.txt* file under */App_Data/admin*, IIS 6.0 will serve the file if requested, potentially exposing the passwords for your package manager instance.

Workaround Rename the *password.txt* or *packagesources.txt* file to *password.config* or *packagesources.config*. By default, IIS 6.0 does not serve files that have the *.config* extension. (In IIS 7, no files in the *App_Data* folder are served, so you do not need to rename the files.)

Issue: Uninstalling packages installed using the Beta 3 release does not completely remove package components

If you installed a package using the package manager in the Beta 3 release and then try to uninstall it using the current release, the package is not completely uninstalled. Using the package manager's **Uninstall** button removes some components, but leaves the package's library code and does not update the *package.config* file.

Workaround
Perform these steps:

1. Delete the *App_Data\packages* folder. This removes all packages.
2. Delete the *packages.config* file in the root of the website.

Issue: In Visual Studio, invoking the web-based package manager takes the application offline

If you are working in Visual Studio (not WebMatrix) and use the *_admin* functionality to start the package manager, Visual Studio takes the application offline and posts the *app_offline.htm* into the website root, which disrupts your ability to use the package manager.

NOTE

Although you would most typically see this behavior when using the web-based package manager interface, the same behavior occurs if you add, remove, or modify any files in the *App_Data* folder.

Workaround

To work with packages in Visual Studio, use the NuGet extension instead of the web-based package manager. For information, see the NuGet documentation. If you are working with other files in the *App_Data* folder, consider keeping the files elsewhere to avoid this issue. If that's not practical, delete the *app_offline.htm* file manually or wait until the site comes back online automatically (by default, after 30 seconds).

Issue: Visual Studio IntelliSense and project templates available only in ASP.NET MVC version 3

Installing ASP.NET Web Pages does not also install tools for Visual Studio such as IntelliSense and project templates for ASP.NET Web Pages applications.

Workaround To use IntelliSense and project templates for ASP.NET Web Pages applications in Visual Studio, install ASP.NET MVC 3 RC either through the Web Platform Installer or the stand-alone installer.

Issue: Reading feeds or other external data via a proxy server

If the server running the site is behind a proxy server, you might need to configure proxy information in the *web.config* file in order to be able to read information that comes from outside your site. For example, if you use the `ReCaptcha` helper, the helper communicates with the reCAPTCHA service, but might be blocked by your proxy server. Similarly, feeds that are used in ASP.NET Web Pages, such as the feed used by the package manager, might require proxy configuration.

If you experience problems in working with an external service or working with the package feed, put the following elements into your application's root *web.config* file:

```
<system.net>
  <defaultProxy>
    <proxy autoDetect="False"
       proxyaddress="[proxy URL]"/>
  </defaultProxy>
</system.net>
```

For more information about configuring a proxy server, see <proxy> Element (Network Settings) on the MSDN Web site.

Issue: Uninstalling the .NET Framework version 4 disables ASP.NET Web Pages with Razor Syntax

If you uninstall the .NET Framework version 4 and then reinstall it, ASP.NET Web Pages with Razor syntax is disabled. Pages with the *.cshtml* extension do not run correctly. ASP.NET Web Pages registers an assembly in the machine root *web.config* file, and removing the .NET Framework removes that file. Reinstalling the .NET Framework installs a new version of the configuration file, but does not add the reference for the ASP.NET Web Pages assembly.

Workaround After reinstalling the .NET Framework, reinstall ASP.NET Web Pages with Razor syntax. This adds the following element to the *web.config* file in the machine root, which is typically in the following location:

```
C:\Windows\Microsoft.NET\Framework\v4.0.30319\Config (32-bit)
C:\Windows\Microsoft.NET\Framework64\v4.0.30319\Config (64-bit)
```

```
<compilation>
  <assemblies>
    <add assembly="System.Web.WebPages.Configuration, Version=1.0.0.0, Culture=neutral,
PublicKeyToken=31bf3856ad364e35" />

    <-- Additional assemblies here. -->

  </assemblies>
</compilation>
```

Issue: Extensionless URLs do not find .cshtml/.vbhtml files on IIS 7 or IIS 7.5

On IIS 7 or IIS 7.5, requests with a URL like the following are not able to find pages that have the *.cshtml* or *.vbhtml* extension:

`http://www.example.com/ExampleSite/ExampleFile`

The issue arises because URL rewriting is not enabled by default for IIS 7 or IIS 7.5. The likeliest scenario is that you do not see the problem when testing locally using IIS Express, but you experience it when you deploy your website to a hosting website.

Workaround

- If you have control over the server computer, on the server computer install the update that is described in A update is available that enables certain IIS 7.0 or IIS 7.5 handlers to handle requests whose URLs do not end with a period.
- If you do not have control over the server computer (for example, you are deploying to a hosting website), add the following to the website's *web.config* file:

```
<system.webServer>
  <modules runAllManagedModulesForAllRequests="true"/>
</system.webServer>
```

Issue: Deploying an application to a computer that does not have SQL Server Compact installed

Applications that include SQL Server Compact databases can run on a computer where SQL Server Compact is not installed. Microsoft WebMatrix 1.0 automatically copies these binaries for you and performs the appropriate *web.config* file transforms.

Workaround If you need to copy these files and make the *web.config* file changes manually, do the following:

1. Copy the database engine assemblies to the *Bin* folder (and subfolders) of the application on the target computer:
   - Copy *C:\Program Files\Microsoft SQL Server Edition\v4.0\Desktop\System.Data.SqlServerCe.dll* **to** *\Bin*
   - Copy *C:\Program Files\Microsoft SQL Server Compact Edition\v4.0\Private\x86* **to** *\Bin\x86*
   - Copy *C:\Program Files\Microsoft SQL Server Compact Edition\v4.0\Private\amd64** **to** *\Bin\amd64*
2. In the root folder of the website, create or open a *web.config* file. (In WebMatrix 1.0, this file type is available if you click **All** in the **Choose a File Type** dialog box.)
3. Add the following element as a child of the `<configuration>` element (not inside the `<system.web>` element):

```
<system.data>
  <DbProviderFactories>
    <remove invariant="System.Data.SqlServerCe.4.0"></remove>
    <add name="Microsoft SQL Server Compact Data Provider"
      invariant="System.Data.SqlServerCe.4.0"
      Description=".NET Framework Data Provider for Microsoft SQL Server Compact"
      type="System.Data.SqlServerCe.SqlCeProviderFactory, System.Data.SqlServerCe, Version=4.0.0.0,
Culture=neutral, PublicKeyToken=89845dcd8080cc91"/>
  </DbProviderFactories>
</system.data>
```

Issue: "Database" and "WebGrid" helpers do not work in Medium Trust in Visual Basic

If you are using Visual Basic (creating *.vbhtml* files), the `Database` and `WebGrid` helpers will not work if the application is set to use Medium Trust.

Workaround

If you use Visual Studio 2010, you can resolve this problem by installing the Service Pack 1 release. Until the final version of the SP1 release is available, you can download the Beta version of SP1 from the Microsoft Visual Studio 2010 Service Pack 1 Beta page on the Microsoft Download Center.

If this is not practical, or if you do not use Visual Studio 2010, you can temporarily set the application to use Full Trust.

Issue: "ApplicationPart" resources are externally accessible

If an assembly contains objects that derives from the `ApplicationPart` class, that assembly's resources are exposed by the `ResourceRouteHandler` class. For example, consider the following URL:

`~/r.ashx/System.Web.WebPages.Administration/Resources/AdminResources.resources`

This request downloads all of the resource strings in the *System.Web.WebPages.Administration.dll* assembly. All of the embedded resources (even those that are not intended to be served as static content) are downloaded. If the embedded resources contain sensitive information, this can represent a security risk.

Workaround

If you create an **ApplicationPart** object, make sure that the embedded resources associated with that **ApplicationPart** object's assembly do not contain sensitive information.

WebMatrix

> **NOTE**
>
> For information about installation issues for WebMatrix, see WebMatrix Installation Issues earlier in this document.

This section of the document describes known issues for the WebMatrix development environment.

Issue: Changes in the username or password of a database connection string in a web.config file are not reflected in the Databases workspace

Workaround

1. In the *web.config* file, change the database name in the connection string (for example, add "1" to it).
2. Save the *web.config* file.
3. Click **Databases** and refresh.
4. Change the database name in the connection string in the *web.config* file back to the original database name.

5. Save the *web.config* file.
6. Click **Databases** and refresh.

Issue: Folders created by WebMatrix cannot be deleted

If WebMatrix is running using elevated permissions (that is, you started WebMatrix using the **Run as Administrator** option in Windows), folders that are created by WebMatrix cannot be deleted using Windows Explorer.

Workaround

Run Windows Explorer using elevated permissions. Follow these steps:

1. In Windows, click **Start**.
2. Enter "Windows Explorer" and right-click the entry for **Windows Explorer**.
3. Click **Run as Administrator**. You can then delete the folders.

Issue: WebMatrix 1.0 is unable to perform certain tasks that require elevation

WebMatrix 1.0 is unable to perform certain tasks that require elevation, such as installing additional components in the following situations:

- On Windows Vista or Windows 7, you are logged in with an account that does not have administrative privileges and User Account Control (UAC) is disabled.
- You are using Microsoft Windows XP or Microsoft Windows Server 2003.

Workaround

Most tasks in WebMatrix 1.0 do not require administrative permission. For those that do, you can perform the operation as an administrator, or follow these steps:

- On Windows Vista or Windows 7, enable UAC.
- On Windows XP, add the user to the Administrators security group.

Issue: "Site from Web Gallery" is disabled

The **Site from Web Gallery** option is disabled if the Web Platform Installer 3.0 is not installed.

Workaround

Install the Microsoft Web Platform Installer 3.0.

Issue: Google Chrome is not available as a Run option

Google Chrome is not displayed in the list of browsers under **Run** on the **Home** tab.

Workaround

Some versions of Google Chrome do not register themselves correctly with the Default Programs feature in Windows. As a workaround, start Google Chrome, click the *Customize and control Google Chrome* menu, click *Options*, and then click *Make Google Chrome my default browser*.

Issue: The "Foreign Key" dialog box doesn't allow entering a primary key

The **Foreign Key** dialog box does not allow you to enter the primary key name from the primary key table.

Workaround

This is intentional. You do not need to enter the name of the primary key from the primary key table.

Issue: IntelliSense is not available in WebMatrix for Razor syntax, C#, or Visual Basic

IntelliSense is supported in WebMatrix for HTML and CSS. However, it is not available for other languages.

Workaround
None.

Issue: IntelliSense for HTML and CSS suggests elements that are not contextually appropriate

IntelliSense for markup in WebMatrix supports HTML using the XHTML 1.0 Transitional schema and CSS using the CSS 2.1 schema. Because IntelliSense is based on these specific schemas, certain tags, attributes, or properties might be suggested that are not appropriate for the current page or style definition. For HTML, it can also lead to unexpected suggestions in content that might be interpreted as malformed XHTML (for example, when tags are not closed). This issue might be more noticeable if the insertion point is inside an incomplete tag; in that case, IntelliSense might suggest new opening tags or offer other incorrect suggestions.

Workaround
For HTML, make sure that you are working within a well-formed, complete XHTML page. For CSS, there is no workaround.

Issue: IntelliSense is not invoked while you type

At times, IntelliSense might not be invoked as HTML or CSS is being entered in the editor. In particular, this might happen when the insertion point is directly next to another element or at the end of a file.

Workaround
Make sure that there is whitespace around the insertion point and that the insertion point is not at the end of a file. You can also invoke IntelliSense manually by pressing Ctrl+Space.

Issue: No UI is available for disabling IntelliSense

WebMatrix 1.0 provides no UI or gesture for disabling IntelliSense.

Workaround
Start WebMatrix using the following command, which includes a switch that disables IntelliSense:

```
WebMatrix.exe #ExecuteCommand# EditorIntelliSense off
```

IIS Express

IIS Express has its own readme file, which is available at the following URL:

https://go.microsoft.com/fwlink/?LinkID=207675&clcid=0x409

SQL Server Compact

SQL Server Compact has its own readme file, which is available at the following URL:

https://go.microsoft.com/fwlink/?LinkID=208545

For information about issues that involve installing SQL Server Compact as part of WebMatrix, see WebMatrix Installation Issues earlier in this document.

Installing Applications

Issue: Installing an application can take a long time if the user's My Documents folder is redirected to a network share

Workaround
None. The application might take a while to install, but will install correctly.

Publishing Applications

Issue: "Required permissions cannot be acquired" error when publishing a SQL Compact Database

WebMatrix does not fully support deploying supporting binaries for SQL Server Compact to a server that is running .NET Framework version 3.5 with a medium trust configuration.

Workaround

The preferred workaround is to install the .NET Framework 4 on the server. Alternatively, do the following:

1. Add the following elements to the `SecurityClasses` section in *Web_MediumTrust.config* file:

```
<SecurityClass Name="ReflectionPermission"
  Description="System.Security.Permissions.ReflectionPermission, mscorlib,
    Version=2.0.0.0, Culture=neutral, PublicKeyToken=b77a5c561934e089"/>

<SecurityClass Name="RegistryPermission"
  Description="System.Security.Permissions.RegistryPermission, mscorlib,
  Version=2.0.0.0, Culture=neutral, PublicKeyToken=b77a5c561934e089"/>
```

2. Create a new permission set in the *Web_MediumTrust.config* file with the following required permissions:

```
<PermissionSet class="NamedPermission" version="1" Name="SqlCe_Trust">
  <IPermission class="SecurityPermission" version="1" Flags="UnmanagedCode,SkipVerification"/>
  <IPermission class="EnvironmentPermission" version="1" Read="PROCESSOR_ARCHITECTURE"/>
  <IPermission class="RegistryPermission" version="1" Read="HKEY_LOCAL_MACHINE\" />
</PermissionSet>
```

3. Apply the permission set to SQL Server Compact by putting the following elements in the *Web_MediumTrust.config* file:

```
<CodeGroup class="UnionCodeGroup" version="1" PermissionSetName="ASP.Net">
  <IMembershipCondition class="UrlMembershipCondition" version="1" Url="$AppDirUrl$/*"/>
  <CodeGroup class="UnionCodeGroup"
      version="1"
      PermissionSetName="SqlCe_Trust"
      Name="SqlCe_Strong_Name"
      Description="This code group grants code signed with the SQLCE strong name SqlCe_Trust. ">
    <IMembershipCondition class="StrongNameMembershipCondition"
      version="1"

PublicKeyBlob="002400000480000094000000060200000024000052534131000400000100010027273 6ad6e5f9586bac2d
531eabc3acc666c2f8ec879fa94f8f7b0327d2ff2ed523448f83c3d5c5dd2dfc7bc99c5286b2c125117bf5cbe242b9d41750
732b2bdffe649c6efb8e5526d526fdd130095ecdb7bf210809c6cdad8824faa9ac0310ac3cba2aa0523567b2dfa7fe250b30
facbd62d4ec99b94ac47c7d3b28f1f6e4c8" Name="System.Data.SqlServerCe" />
  </CodeGroup>
</CodeGroup>
```

Issue: Gallery and PhpBB web applications display a "Service is unavailable" error after publishing

Under some circumstances, publishing an application causes a "service is unavailable" error.

Workaround

In WebMatrix, add a backslash () to the end of the server name in the **Publish Settings** window and then publish the application again.

Issue: Moodle website layout and links are broken after publishing

After you publish a Moodle application, the application does not work correctly.

Workaround

In WebMatrix, add a slash (/) to the end of the **Site Name** field in the **Publish Settings** window and then

publish the application again.

Issue: Publishing nopCommerce fails with a database error

Publishing nopCommerce fails and reports a database error like "Insert into the nop_log table failed."

Workaround

1. In WebMatrix, click **Run** to launch nopCommerce locally.
2. Log into the administration page.
3. Click the **System** menu.
4. Click the **Log** option.
5. Click the **Clear Log** button.
6. Publish nopCommerce again.

Issue: Silverstripe CMS displays a "HTTP 500 PHP FCGI Error" when you download a published site

Workaround
After you click **Download published site**, skip `silverstripe-cache/manifest_main` in **Publish Preview**. This file is used for caching purposes and is specific to each computer.

Issue: Subtext displays "Server Error in '/' Application" when you download a published site

Workaround
Open the site's *web.config* file and replace the user ID and password in the database connection string with the SQL Server administrator credentials (the "sa" credentials).

Alternatively, follow these steps in order to give the user account you are logged in with `db_owner` permissions:

1. Install SQL Server Management Studio using the Web Platform Installer.
2. Connect to the local SQL Server Express instance (by default, `.\SQLEXPRESS`).
3. Click **Databases** > *[localSubtextDatabase]* > **Security** > **Users** > *[localSubtextUser]* (default is `subtextuser`], right-click, and click **Properties**.
4. Select **db_owner** in the role membership section.

Issue: Site might not work after publishing if the "Destination URL" field is not prefixed with http:// or https://

In the **Publishing Settings** dialog box, if the destination URL does not begin with `http://` or `https://`, the site might not work after deployment.

Workaround
Make sure that before you publish a site, the destination URL in the **Publish Settings** dialog box starts with `http://` or `https://`.

Issue: Publishing a MySQL database fails with the error "Failed to publish the database. This can happen if the remote database cannot run the script."

The error can occur for a number of reasons. One reason you can see this error is if the database script contains a single quotation character (') and the destination MySQL database's default character set is not to UTF-8.

Workaround
Set the default character set for the remote MySQL database to UTF-8.

Issue: Some links are not visible in DotNetNuke after publishing or downloading the site

If you publish or download a DotNetNuke site, you might need to clear the cache to get the new links to appear on the site.

Workaround

1. Log in as "Host".
2. Go to the host menu and select **Host Settings**.
3. Scroll down and under **Advanced Settings**, expand **Performance Settings**.
4. Click the **Clear Cache** link for pages.
5. Go to the bottom of the page and restart the application.

Issue: Some links in AtomSite are broken after you download a published site

Workaround

In the *service.config* file, *users.config* file, and all *.xml* files, replace the URL string (for example, `http://myhost.com/atomsite`) with the local one (for example, `http://localhost:1239`).

Issue: MySQL-based applications like WordPress fail to publish and report a database error

By default, WebMatrix installs MySQL with the UTF-8 character set. If you install MySQL on your own, and the character set is not UTF-8 (for example, it is Latin1), the publish process for databases might fail.

Workaround

1. Change the character set for MySQL to UTF-8. (For details, see Server Character Set and Collation on the MySQL website.)
2. Reinstall the application.
3. Republish the application.

Issue: "Download published site" fails for applications that have browser-based setup

Some applications (for example, Kentico CMS) require you to launch them in the browser in order to perform post-installation setup such as creating a database. If you publish an application like this without completing the browser-based setup, attempting to download the same site from a remote server will fail.

Workaround

Finish browser-based setup before publishing the site.

Issue: "Download published site" fails with a database error for DotNetNuke and Kooboo CMS

If you try to download an application from a server and you have administrator credentials in the database connection string in the **Publish Settings** dialog, you might see the following error in the publish log:

```
1:28:29 PM: An error occurred during execution of the database script. The approximate location of the
error was between lines '3260' and '3262' of the script. The verbose log may have more information about
the error. The command started with:

1:28:29 PM: CREATE LOGIN [MACHINE\Administrator] FROM WINDOW

1:28:29 PM: https://go.microsoft.com/fwlink/?LinkId=178587.
```

Workaround

If practical, republish the site (or have it published) using non-administrator credentials for the database.

  - SQL Server Compact
  - Installing Applications
  - Publishing Applications
  - Other Issues
- For More Information

Overview

> Microsoft WebMatrix Beta is a free web development stack that installs in minutes. It integrates a web server with database and programming frameworks to create a single, integrated experience. You can use WebMatrix Beta to streamline the way you code, test, and publish your own ASP.NET or PHP website, or you can use WebMatrix Beta to start a new website using popular open-source apps like DotNetNuke, Umbraco, WordPress, or Joomla. WebMatrix Beta uses the same powerful web server, database engine, and frameworks environment that will run your website on the internet, which makes the transition from development to production smooth and seamless.

Installation

> To install WebMatrix Beta 3, you use Microsoft Web Platform Installer 3.0. After you've installed the Web Platform Installer, you can use it to install WebMatrix Beta 3.
>
> If you have problems during installation, refer to Troubleshooting Problems with Microsoft Web Platform Installer.

Instructions for Publishing Applications

> See Step-by-Step Instructions for Publishing Applications

New Features, Changes, andKnown Issues

WebMatrix Beta 3 Installation

Issue: WebMatrix Beta 3 is only available on platforms that support Microsoft .NET Framework 4

The .NET Framework version 4 is required for WebMatrix Beta. In certain cases, the WebMatrix Beta installer will let you try to install on a platform that is not part of the supported configuration set. In particular, Windows Vista without the SP1 update will let you begin the installation of WebMatrix Beta, but the .NET Framework 4 component will fail and block your installation.

Workaround

Install on a supported platform, which includes:

- Windows 7
- Windows Server 2008
- Windows Server 2008 R2
- Windows Vista SP1 or later
- Windows XP SP3
- Windows Server 2003 SP2

Issue: Cannot install WebMatrix Beta 3 if Microsoft Visual Studio 2008 is installed without Microsoft Visual Studio 2008 SP1

Workaround

Install Microsoft Visual Studio 2008 SP1 from the Microsoft Download Center.

Issue: Some assemblies for SQL Server Compact 4.0 are not installed in the GAC

The managed assemblies for SQL Server Compact 4.0 are not placed in the global assembly cache (GAC) when you install SQL Server Compact 4.0 on a 64-bit computer and the computer has only the .NET Framework 3.5 SP1 Client Profile installed. The managed assemblies that are not installed in the GAC are:

- *System.Data.SqlServerCe.dll* (ADO.NET provider)
- *System.Data.SqlServerCe.Entity.dll* (ADO.NET Entity Framework)

Workaround

Uninstall SQL Server Compact 4.0. Download and install the full version of .NET Framework 3.5 SP1 from the following location:

Microsoft .NET Framework 3.5 Service pack 1 (Full Package)

Then reinstall SQL Server Compact 4.0.

Issue: Cannot uninstall SQL Server Compact using the command line

Uninstallation of SQL Server Compact using command-line options does not work in this release.

Workaround

Use *Programs and Features* in the Windows Control Panel to uninstall Microsoft SQL Server Compact 4.0.

ASP.NET Web Pages

This section of the document describes new features, changes, and known issues with the Beta 3 release of ASP.NET Web Pages with Razor syntax.

- New features
- Changes
- Issues

New Features in Beta 3 for ASP.NET Web Pages with Razor Syntax

New: "Html.Raw" method renders unencoded markup

The new `Html.Raw` method lets you render HTML markup as markup instead of rendering encoded output. (By default, ASP.NET Razor encodes strings before rendering them.) The syntax is:

`Html.Raw(value)`

The following example shows how to use `Html.Raw`:

```
@* Inserts literal markup into the page as specified in the value string. *@
@Html.Raw("<div>Hello <em>world</em>!</div>")
```

Changes in Beta 3 for ASP.NET Web Pages with Razor Syntax

Change: "HrefAttribute" method removed

The `HrefAttribute` method of the `WebPage` class has been removed. This helper was used to encode unsafe characters in URLs. It is no longer required because ASP.NET Razor automatically encodes strings. (Use the new `Html.Raw` method to render unencoded strings.)

Change: Syntax for declarative "@helper" helpers changed

In the Beta 3 release, ASP.NET changes how it parses helpers that are created using the `@helper` syntax. In essence, the `@helper` syntax is now parsed as a code block instead of as a block of markup that can include code. Therefore, code inside the helper does not need to be enclosed in `@{ }` blocks. Conversely, markup inside the helper has to be explicitly included in HTML elements or in ASP.NET Razor `<text></text>` tags.

For example, the following `@helper` syntax works in the Beta 3 release:

```
@helper ThumbnailLink(string imagePath, int width, int height) {
    @{
        string newFileName = "";
        WebImage thumbnail = new WebImage(imagePath);
        if(thumbnail != null){
           thumbnail.Resize(width, height, true, true);
           newFileName = @"~\thumb_" + Path.GetFileName(thumbnail.FileName);
           thumbnail.Save(newFileName);
        }
    }
    <a href="@Href(imagePath)"><img src="@Href(newFileName)" /></a>
}
```

In the Beta 3 release, this helper must be changed to look like the following example:

```
@helper ThumbnailLink(string imagePath, int width, int height) {
    string newFileName = "";
    WebImage thumbnail = new WebImage(imagePath);
    if(thumbnail != null){
       thumbnail.Resize(width, height, true, true);
       newFileName = @"~\thumb_" + Path.GetFileName(thumbnail.FileName);
       thumbnail.Save(newFileName);
    }
    <a href="@Href(imagePath)"><img src="@Href(newFileName)" /></a>
}
```

Notice that the `@{ }` characters around the initial code in the helper is no longer used. This is because the contents of the helpers are treated as a code block by default. The helper renders markup, which starts with the opening `<a>` tag. If the helper must render plain text or tags that do not include a closing tag (for example,

`<meta>` tags), the content to be rendered must be in `<text></text>` tags.

Change: "WebPageContext.HttpContext" removed

The `WebPageContext.HttpContext` property has been removed. Use `HttpContext.Current` instead. (The `WebPageContext.HttpContext` property simply wrapped this.)

Change: "Facebook" helper moved to new package

The `Facebook` helper has been moved to the *Facebook.Helper* library, which includes the `Facebook` helper and additional functionality. You must install this library as a separate package, as described in "Installing Helpers with Package Manager" in the tutorial Getting Started with ASP.NET Pages.

Change: Membership, Role, and Security types moves to new assembly

The following types were moved to the `WebMatrix.WebData` assembly:

- `ExtendedMembershipProvider`
- `SimpleMembershipProvider`
- `SimpleRoleProvider`
- `WebSecurity`

Change: "TagBuilder" class moved to System.Web.WebPages.dll assembly

The `TagBuilde` r class has been moved to the System.Web.WebPages.dll assembly. Previously, this was in an assembly that was part of ASP.NET MVC. This change means that you do not have to install ASP.NET MVC in order to use the `TagBuilder` class.

However, the class is still in the `System.Web.Mvc` namespace. In order to use the `TagBuilder` class (for example, in a custom ASP.NET Razor helper), you must reference the namespace (for example, by adding `@using System.Web.Mvc` to your code).

Change: Request validation syntax changed; "Validation" class removed

In the Beta 3 release, to disable validation for an individual field or set of fields, you can call the `Validation.Exclude` method, passing in the name or names of the fields to exclude from validation. A new syntax is available in the Beta 3 release for bypassing validation. The `Validation` method used in Beta 3 has been removed.

> **NOTE**
>
> If you do not disable request validation, if users try to upload HTML markup (for example, by using a rich text editor on a page), the website will report an error like *A potentially dangerous Request.Form value was detected from the client* and the user input is not accepted. If you disable request validation, you must manually check user input to make sure that it does not contain potentially dangerous markup or script using something like the Microsoft Anti-Cross Site Scripting Library V4.0.

To disable automatic request validation, call the `Request.Unvalidated` method, passing it the name of the field or other post object that you want to bypass request validation for. You can use this method to bypass validation for any items in the `Form`, `QueryString`, `Cookies`, and `ServerVariables` collections. The following examples show how to use the `Unvalidated` method:

```
Request["userInput"]; // Validated
Request.Unvalidated("userInput"); // Validation bypassed
Request.Unvalidated().Form["userInput"]; // Validation bypassed

Request.QueryString["userPreference"]; // Validated
Request.Unvalidated().QueryString["userPreference"]; // Validation bypassed
```

Known Issues for ASP.NET Web Pages with Razor Syntax

Issue: Unexpected behavior when using a custom user table for membership

To initialize the membership provider for an ASP.NET Razor website, you call the `WebSecurity.InitializeDatabaseConnection` method. (In WebMatrix, the Starter Site template includes a call to this method in the *_AppStart.cshtml* file.) If the `autoCreateTables` parameter of this method is set to true (by default, it is set to true in the Starter Site template), and if an unrecognized table name is passed to the method (the second parameter), the method does not throw an error. Instead, it automatically creates the table.

This can be a problem if you intend to use a custom user table for membership but pass the wrong table name to the `WebSecurity.InitializeDatabaseConnection` method. Because the method does not by default raise an error if the table you specify does not exist, and because it instead creates a new table, the application can appear to be working. However, application code that relies on your custom user table (and on fields in it) can eventually fail with unexpected errors.

Workaround

Make sure that the name passed in the `InitializeDatabaseConnection` method matches the user profile table in the membership database, or make sure that the `autoCreateTables` parameter is set to false.

Issue: "Failed to generate a user instance of SQL Server" error

If a WebMatrix Web application uses SQL Server Express and is running IIS 7.5 on Windows 7 or Windows Server 2008 R2, you might see an error that indicates that SQL Server cannot retrieve the user's local application path at run time.

Workaround Make sure that the Windows account that the application runs under (typically NETWORK SERVICE) has read/write permissions for root folders of the application and for subfolders such as *App_Data*. More detailed information is available in the KnowledgeBase article Problems with SQL Server Express user instancing and ASP.net Web Application Projects.

Issue: In Visual Studio, namespaces for custom assemblies (DLLs) are not imported automatically

If you use custom assemblies in a project in Visual Studio, the namespaces declared in those assemblies are not automatically imported at design time. As a result, references to custom types might not be recognized at design time and are marked as not recognized in Visual Studio (using a "squiggle"). This problem occurs only at design time in Visual Studio; the application itself runs properly.

Workaround

Include a `using` statement (`imports` in Visual Basic) that references the entities that are not recognized at design time.

Issue: Visual Studio IntelliSense and project templates available only in ASP.NET MVC version 3

Installing ASP.NET Web Pages does not also install tools for Visual Studio such as IntelliSense and project templates for ASP.NET Web Pages applications.

Workaround To use IntelliSense and project templates for ASP.NET Web Pages applications in Visual Studio, install ASP.NET MVC 3 RC either through the Web Platform Installer or the stand-alone installer.

Issue: "<helper> class cannot be found" error

After you upgrade to Beta 3, you might see an error that a helper class (for example, the `Facebook` class) cannot not be found. Starting in Beta 2 and continuing in Beta 3, helpers have been moved to packages that you must explicitly install. Existing sites are not upgraded to include these packages; this includes sites in the *\My Documents\IISExpress* or *\My Documents\My Web Sites* folders. In particular, you will see this error if you use the default site in *My Sites* (WebSite1), which includes a reference to the `Twitter` helper.

Workaround
Comment out calls to any helpers in the site, run the *_Admin* page, and install the package or packages that include the helpers that you want to use. After you've installed the package, you can uncomment the lines that reference helpers.

Issue: Deploying Beta 3 ASP.NET Razor assemblies to the Bin folder might not work on hosting sites

If you deploy an ASP.NET Web Pages website to a hosting site, and if you deploy the ASP.NET Razor Beta 3 assemblies to the site's *Bin* folder, you might experience errors, including the following:

```
Could not load type 'Microsoft.Web.Infrastructure.DynamicModuleHelper.DynamicModuleUtility' from assembly
'Microsoft.Web.Infrastructure, Version=1.0.0.0, Culture=neutral, PublicKeyToken=31bf3856ad364e35'.
```

This can happen if the hosting provider has installed the ASP.NET Web Pages Beta 1 assemblies into the server's global application cache (GAC). Assemblies in the GAC get precedence over assemblies installed locally in the *Bin* folder.

Workaround Contact your hosting provider to confirm that the errors you are seeing are due to a conflict between the provider's versions of the assemblies and yours. If so, request that the hosting provider update the assemblies in the server's GAC.

Issue: Reading feeds or other external data via a proxy server

If the server running the site is behind a proxy server, you might need to configure proxy information in the *Web.config* file in order to be able to read information that comes from outside your site. For example, if you use the `ReCaptcha` helper, the helper communicates with the reCAPTCHA service, but might be blocked by your proxy server. Similarly, feeds that are used in ASP.NET Web Pages, such as the feed used by the package manager, might require proxy configuration.

If you experience problems in working with an external service or working with the package feed, put the following elements into your application's root *Web.config* file:

```
<system.net>
  <defaultProxy>
    <proxy autoDetect="False"
       proxyaddress="[proxy URL]"/>
  </defaultProxy>
</system.net>
```

For more information about configuring a proxy server, see <proxy> Element (Network Settings) on the MSDN Web site.

Issue: "Microsoft.Web.Infrastructure.dll cannot be loaded" error

If you previously installed the Beta 1 version of ASP.NET Web Pages with Razor syntax and then install the Beta 3 version, all appropriate assemblies are installed in the GAC except *Microsoft.Web.Infrastructure.dll*. As a consequence, when you run ASP.NET Razor pages, you see an error that indicates that *Microsoft.Web.Infrastructure.dll* could not be loaded.

This issue does not occur if you loaded the Beta 3 release on a clean computer.

Workaround

In Control Panel, uninstall ASP.NET Web Pages. Then reinstall the Beta 3 release.

Issue: Uninstalling the .NET Framework version 4 disables ASP.NET Web Pages with Razor Syntax

If you uninstall the .NET Framework version 4 and then reinstall it, ASP.NET Web Pages with Razor syntax is disabled. Pages with the *.cshtml* extension do not run correctly. ASP.NET Web Pages registers an assembly in the machine root *Web.config* file, and removing the .NET Framework removes that file. Reinstalling the .NET Framework installs a new version of the configuration file, but does not add the reference for the ASP.NET Web Pages assembly.

Workaround After reinstalling the .NET Framework, reinstall ASP.NET Web Pages with Razor syntax. This adds the following element to the *Web.config* file in the machine root, which is typically in the following location:

`C:\Windows\Microsoft.NET\Framework\v4.0.30319\Config (32-bit)`

`C:\Windows\Microsoft.NET\Framework64\v4.0.30319\Config (64-bit)`

```
<compilation>
  <assemblies>
    <add assembly="Microsoft.WebPages.Configuration, Version=1.0.0.0, Culture=neutral,
PublicKeyToken=31bf3856ad364e35" />

    <-- Additional assemblies here. -->

  </assemblies>
</compilation>
```

Issue: Applications previously deployed with ASP.NET assemblies in the Bin folder experience errors

During deployment, copies of the ASP.NET Web Pages assemblies (for example, *Microsoft.WebPages.dll*) to the *Bin* folder of the website on the server. (This might have happened automatically during deployment or because the developer explicitly copied the assemblies.) However, when the Beta 3 release is installed, errors occurs, such as errors that certain types cannot be found. This occurs because a number of ASP.NET Web Pages types were moved into different namespaces for the Beta 3 release.

Workaround

Clear the *Bin* folder of the deployed application, copy the new assemblies to the folder (or redeploy the application), and then restart the application.

Issue: Extensionless URLs do not find .cshtml/.vbhtml files on IIS 7 or IIS 7.5

On IIS 7 or IIS 7.5, requests with a URL like the following are not able to find pages that have the *.cshtml* or *.vbhtml* extension:

`http://www.example.com/ExampleSite/ExampleFile`

The issue arises because URL rewriting is not enabled by default for IIS 7 or IIS 7.5. The likeliest scenario is that you do not see the problem when testing locally using IIS Express, but you experience it when you deploy your website to a hosting website.

Workaround

- If you have control over the server computer, on the server computer install the update that is described in A update is available that enables certain IIS 7.0 or IIS 7.5 handlers to handle requests whose URLs do not end with a period.

- If you do not have control over the server computer (for example, you are deploying to a hosting website), add the following to the website's *Web.config* file:

```
<system.webServer>
  <modules runAllManagedModulesForAllRequests="true"/>
</system.webServer>
```

Issue: Using Web Application Project or ASP.NET MVC and ASP.NET Web pages in the same application

If you were using ASP.NET Web Pages in a Web Application project or ASP.NET MVC application, you might see an error that *WebPageHttpApplication* cannot be found.

Workaround

If you get this error, change the base class from which the application derives. In the *Global.asax* file, change the following line:

```
public class MvcApplication :  WebPageHttpApplication { ... }
```

To this:

```
public class MvcApplication :  HttpApplication { ... }
```

This in effect reverses a change that was introduced for the Beta 1 release of ASP.NET Web Pages with Razor syntax.

Issue: Deploying an application to a computer that does not have SQL Server Compact installed

Applications that include SQL Server Compact databases can run on a computer where SQL Server Compact is not installed. Microsoft WebMatrix Beta 3 automatically copies these binaries for you and performs the appropriate *Web.config* file transforms.

Workaround If you need to copy these files and make the *Web.config* file changes manually, do the following :

1. Copy the database engine assemblies to the *Bin* folder (and subfolders) of the application on the target computer:
   - Copy *C:\Program Files\Microsoft SQL Server Compact Edition\v4.0\Desktop\System.Data.SqlServerCe.dll* to *\Bin*
   - Copy *C:\Program Files\Microsoft SQL Server Compact Edition\v4.0\Private\x86** to *\Bin\x86*
   - Copy *C:\Program Files\Microsoft SQL Server Compact Edition\v4.0\Private\amd64** to *\Bin\amd64*
2. In the root folder of the website, create or open a *Web.config* file. (In WebMatrix Beta 3, this file type is available if you click **All** in the **Choose a File Type** dialog box.)
3. Add the following element as a child of the **<configuration>** element (not inside the **<system.web>** element):

```
<system.data>
  <DbProviderFactories>
    <remove invariant="System.Data.SqlServerCe.4.0"></remove>
    <add name="Microsoft SQL Server Compact Data Provider"
      invariant="System.Data.SqlServerCe.4.0"
      Description=".NET Framework Data Provider for Microsoft SQL Server Compact"
      type="System.Data.SqlServerCe.SqlCeProviderFactory, System.Data.SqlServerCe, Version=4.0.0.0,
Culture=neutral, PublicKeyToken=89845dcd8080cc91"/>
  </DbProviderFactories>
</system.data>
```

Issue: Database and WebGrid helpers do not work in Medium Trust in Visual Basic

If you are using Visual Basic (creating *.vbhtml* files), the `Database` and `WebGrid` helpers will not work if the application is set to use Medium Trust.

Workaround

Temporarily set the application to use Full Trust.

SQL Server Compact

Issue: "Encrypt" property is not recognized

SQL Server Compact 4.0 does not recognize the `Encrypt` property of the `SqlCeConnection` class. You should not use this property to encrypt database files. The `Encrypt` property was deprecated in SQL Server Compact 3.5 release and was retained only for backward compatibility.

Workaround

Use the `Encryption Mode` property of the `SqlCeConnection` class to encrypt SQL Server Compact 4.0 database files. The following example shows how to create an encrypted SQL Server Compact 4.0 database using the `Encryption Mode` property:

```
SqlCeEngine engine = new SqlCeEngine("Data Source=Northwind.sdf;encryption mode=platform default;Password=
<enterStrongPasswordHere>;");
engine.CreateDatabase();
```

```
Dim engine As SqlCeEngine = New SqlCeEngine("Data Source=Northwind.sdf;encryption mode=platform
default;Password=<enterStrongPasswordHere>;")
engine.CreateDatabase()
```

To change the encryption mode of an existing SQL Server Compact 4.0 database, do the following:

```
SqlCeEngine engine = new SqlCeEngine("Data Source=Northwind.sdf;Password=<enterStrongPasswordHere>;");
engine.Compact("Data Source=Northwind.sdf;encryption mode=ppc2003 compatibility;Password=
<enterStrongPasswordHere>;");
```

```
Dim engine As SqlCeEngine = New SqlCeEngine("Data Source=Northwind.sdf;Password=
<enterStrongPasswordHere>;")
engine.Compact("Data Source=Northwind.sdf;encryption mode=ppc2003 compatibility;Password=
<enterStrongPasswordHere>;")
```

To encrypt an unencrypted SQL Server Compact 4.0 database, do the following:

```
SqlCeEngine engine = new SqlCeEngine("Data Source=Northwind.sdf");
engine.Compact("Data Source=Northwind.sdf;encryption mode=platform default;Password=
<enterStrongPasswordHere>;");
```

```
Dim engine As SqlCeEngine = New SqlCeEngine("Data Source=Northwind.sdf;")
engine.Compact("Data Source=Northwind.sdf;encryption mode=platform default;Password=
<enterStrongPasswordHere>;")
```

Issue: Microsoft Visual C++ 2008 runtime libraries are required

The native DLLs of SQL Server Compact 4.0 need the Microsoft Visual C++ 2008 Runtime Libraries (x86, IA64, and x64), Service Pack 1.

Workaround

Install the .NET Framework 3.5 SP1. This also installs the Visual C++ 2008 Runtime Libraries SP1. You can download the libraries from the following location:

Microsoft Visual C++ 2008 Service Pack 1 Redistributable Package ATL Security Update

> **NOTE**
>
> Note that installing the .NET Framework 2.0, 3.0, or 4 does *not* install the Visual C++ 2008 Runtime Libraries SP1.

Issue: If SQL Server Compact is installed prior to installing .NET Framework on the computer, its provider invariant name is not registered in the .NET Framework machine.config file

SQL Server Compact can be installed on a machine that does not have .NET Framework installed because SQL Server Compact does require the .NET framework. If neither .NET Framework version 3.5 nor 4 is installed before you install SQL Server Compact, the SQL Server Compact Setup does not register its provider invariant name in the *machine.config* file. Any application that relies on the SQL Server Compact entry in the *machine.config* file will fail. The invariant name registration entry in *machine.config* looks like the following example:

```
<system.data>
  <DbProviderFactories>
    <remove invariant="System.Data.SqlServerCe.4.0"></remove>
    <add
name="Microsoft SQL Server Compact Data Provider"
invariant="System.Data.SqlServerCe.4.0"
        Description=".NET Framework Data Provider for Microsoft SQL Server Compact"
        type="System.Data.SqlServerCe.SqlCeProviderFactory, System.Data.SqlServerCe,
Version=4.0.0.0, Culture=neutral, PublicKeyToken=89845dcd8080cc91"/>
    </DbProviderFactories>
</system.data>
```

Workaround

Uninstall SQL Server Compact 4.0 CTP1. Download and install the full versions of the .NET Framework from the following location:

Microsoft .NET Framework 3.5 Service pack 1 (Full Package)
Microsoft .NET Framework 4.0 Release (Full Package)

Then reinstall SQL Server Compact 4.0 CTP1.

Installing Applications

Issue: Installing an application can take a long time if the user's My Documents folder is redirected to a network share

Workaround
None. The application might take a while to install, but will install correctly.

Publishing Applications

Issue: Site might not work after publishing if the "Destination URL" field is not prefixed with http:// or https://

In the **Publishing Settings** dialog box, if the destination URL does not begin with `http://` or `https://`, the site might not work after deployment.

Workaround
Make sure that before you publish a site, the destination URL in the **Publish Settings** dialog box starts with `http://` or `https://`.

Issue: Publishing a MySQL database fails with the error "Failed to publish the database. This can happen if the remote database cannot run the script."

The error can occur for a number of reasons. One reason you can see this error is if the database script contains a single quotation character (') and the destination MySQL database's default character set is not to UTF-8.

Workaround
Set the default character set for the remote MySQL database to UTF-8.

Other Issues

Issue: Search/Filter does not work in Reports for Group By: Issue Type

When you run a report for a site, if you enter text in the *Filter by URL* box and click *Search*, nothing happens. This is because this control is not functional while the *Group By* state of the report is set to *Issue Type*, which is the default.

Workaround In the *Group By* tab of ribbon, click *URL* to group the entries by their source URL. The text box and button to filter the entries are functional while in this state.

Issue: WCF applications fail to run with IIS Express

Browsing to a WCF application results in an error like the following one:

Could not load file or assembly 'Microsoft.Web.Administration, Version=7.0.0.0, Culture=neutral,PublicKeyToken=31bf3856ad364e35' or one of its dependencies. The system cannot find the file specified.

This occurs because IIS Express Beta release doesn't support WCF by default.

Workaround Use any one of the following workarounds (workaround #2 requires Microsoft Windows Vista or higher):

1. Copy the *Microsoft.Web.dll* and *Microsoft.Web.Administration.dll* assemblies from the WebMatrix installation location to the *bin* directory of the WCF application. By default, WebMatrix is installed in the *Microsoft WebMatrix* subfolder under the system's *Program Files* folder.

2. On Microsoft Windows Vista or higher, create a symlink to the assemblies in the *bin* directory using the following commands. (This approach has the advantage that it does not create a copy of the assemblies.)

```
mklink Microsoft.Web.Administration.dll "c:\Program Files (x86)\Microsoft
WebMatrix\Microsoft.Web.Administration.dll"
mklink Microsoft.Web.dll "c:\Program Files (x86)\Microsoft WebMatrix\Microsoft.Web.dll"
```

3. Install the two assemblies in the GAC. From an elevated prompt, run the following commands:

```
gacutil /i  "c:\Program Files (x86)\Microsoft WebMatrix\Microsoft.Web.Administration.dll"
gacutil /i "c:\Program Files (x86)\Microsoft WebMatrix\Microsoft.Web.dll"
```

Issue: WebMatrix Beta 3 is unable to perform certain tasks that require elevation

WebMatrix Beta 3 is unable to perform certain tasks that require elevation, such as installing additional components in the following situations:

- On Windows Vista or Windows 7, you are logged in with an account that does not have administrative privileges and User Account Control (UAC) is disabled.
- You are using Microsoft Windows XP or Microsoft Windows Server 2003.

Workaround

Most tasks in WebMatrix Beta 3 do not require administrative permission. For those that do, you can perform the operation as an administrator, or follow these steps:

- On Windows Vista or Windows 7, enable UAC.
- On Windows XP, add the user to the Administrators security group.

Issue: "Site from Web Gallery" is disabled

The **Site from Web Gallery** option is disabled if the Web Platform Installer 3.0 is not installed.

Workaround

Install the Microsoft Web Platform Installer 3.0.

Issue: On Windows Server 2003, IIS Express does not start for a non-administrative user

On Windows Server 2003, when you launch a page or start IIS Express, IIS Express does not start. For Web pages, an error is displayed that indicates that the application has been started by a non-administrative user.

Workaround

Start WebMatrix Beta 3 as an administrative user. For more details, see the following KnowledgeBase article:

An application that is started by a non-administrative user cannot listen to the HTTP traffic of the computer on which the application is running in Windows Vista, Windows Server 2003, or Windows XP.

Issue: Google Chrome is not available as a Run option

Google Chrome is not displayed in the list of browsers under **Run** on the **Home** tab.

Workaround

Some versions of Google Chrome do not register themselves correctly with the Default Programs feature in Windows. As a workaround, start Google Chrome, click the *Customize and control Google Chrome* menu, click *Options*, and then click *Make Google Chrome my default browser*.

Issue: The "Foreign Key" dialog box doesn't allow entering a primary key

The **Foreign Key** dialog box does not allow you to enter the primary key name from the primary key table.

Workaround

This is intentional. You do not need to enter the name of the primary key from the primary key table.

Issue: The "Relationships" button is disabled

The **Relationships** button under the **Table** tab in the **Databases** workspace is disabled for SQL Server Compact databases.

Workaround

None. SQL Server Compact does not support relationships between tables.

Issue: Parameterized SQL queries throw exceptions

In SQL Server Compact 4.0, if you do not specify a data type such as `SqlDbType` or `DbType` for parameters in parameterized queries, an exception is thrown when the query runs.

Workaround

Explicitly set the data type for parameters such as `SqlDbType` or `DbType`. This is critical in the case of BLOB data types (`image` and `ntext`). Use code like the following:

```
SqlCeEngine engine = new SqlCeEngine(connString);
engine.CreateDatabase();
engine.Dispose();
SqlCeConnection conn = new SqlCeConnection(connString);
conn.Open();
SqlCeCommand cmd = conn.CreateCommand();
cmd.CommandText = "CREATE TABLE BlobTable(name nvarchar(128), blob ntext);";
cmd.ExecuteNonQuery();
cmd.CommandText = "INSERT INTO BlobTable(name, blob) VALUES (@name, @blob);";
SqlCeParameter paramName = cmd.Parameters.Add("name", SqlDbType.NVarChar, 128);
SqlCeParameter paramBlob = cmd.Parameters.Add("blob", SqlDbType.NText);
paramName.Value = "Name1";
paramBlob.Value = "Name1".PadLeft(4001);
cmd.ExecuteNonQuery();
```

```
Dim engine As SqlCeEngine = New SqlCeEngine(connString)
engine.CreateDatabase()
engine.Dispose()
Dim conn As SqlCeConnection = New SqlCeConnection(connString)
conn.Open()
Dim cmd As SqlCeCommand = conn.CreateCommand()
cmd.CommandText = "CREATE TABLE BlobTable(name nvarchar(128), blob ntext);"
cmd.ExecuteNonQuery()
cmd.CommandText = "INSERT INTO BlobTable(name, blob) VALUES (@name, @blob);"
Dim paramName As SqlCeParameter
Dim paramBlob As SqlCeParameterparamName = cmd.Parameters.Add("name", SqlDbType.NVarChar, 128)
paramName.Value = "Name1"
paramBlob = cmd.Parameters.Add("blob", SqlDbType.NText)
paramBlob.Value = "Name1".PadLeft(4001)
cmd.ExecuteNonQuery()
```

Configuration builders for ASP.NET

9/16/2020 • 13 minutes to read • Edit Online

By Stephen Molloy and Rick Anderson

Configuration builders provide a modern and agile mechanism for ASP.NET apps to get configuration values from external sources.

Configuration builders:

- Are available in .NET Framework 4.7.1 and later.
- Provide a flexible mechanism for reading configuration values.
- Address some of the basic needs of apps as they move into a container and cloud focused environment.
- Can be used to improve protection of configuration data by drawing from sources previously unavailable (for example, Azure Key Vault and environment variables) in the .NET configuration system.

Key/value configuration builders

A common scenario that can be handled by configuration builders is to provide a basic key/value replacement mechanism for configuration sections that follow a key/value pattern. The .NET Framework concept of ConfigurationBuilders is not limited to specific configuration sections or patterns. However, many of the configuration builders in `Microsoft.Configuration.ConfigurationBuilders` (github, NuGet) work within the key/value pattern.

Key/value configuration builders settings

The following settings apply to all key/value configuration builders in `Microsoft.Configuration.ConfigurationBuilders`.

Mode

The configuration builders use an external source of key/value information to populate selected key/value elements of the configuration system. Specifically, the `<appSettings/>` and `<connectionStrings/>` sections receive special treatment from the configuration builders. The builders work in three modes:

- `Strict` - The default mode. In this mode, the configuration builder only operates on well-known key/value-centric configuration sections. `Strict` mode enumerates each key in the section. If a matching key is found in the external source:
  - The configuration builders replace the value in the resulting configuration section with the value from the external source.
- `Greedy` - This mode is closely related to `Strict` mode. Rather than being limited to keys that already exist in the original configuration:
  - The configuration builders adds all key/value pairs from the external source into the resulting configuration section.
- `Expand` - Operates on the raw XML before it's parsed into a configuration section object. It can be thought of as an expansion of tokens in a string. Any part of the raw XML string that matches the pattern `${token}` is a candidate for token expansion. If no corresponding value is found in the external source, then the token is not changed. Builders in this mode are not limited to the `<appSettings/>` and `<connectionStrings/>` sections.

The following markup from *web.config* enables the EnvironmentConfigBuilder in `Strict` mode:

```
<configuration>

  <configSections>
    <section name="configBuilders"
             type="System.Configuration.ConfigurationBuildersSection,
             System.Configuration, Version=4.0.0.0, Culture=neutral,
             PublicKeyToken=b03f5f7f11d50a3a"
             restartOnExternalChanges="false" requirePermission="false" />
  </configSections>

  <configBuilders>
    <builders>
      <add name="MyEnvironment"
           type="Microsoft.Configuration.ConfigurationBuilders.EnvironmentConfigBuilder,
           Microsoft.Configuration.ConfigurationBuilders.Environment,
           Version=1.0.0.0, Culture=neutral" />
    </builders>
  </configBuilders>

  <appSettings configBuilders="MyEnvironment">
    <add key="ServiceID" value="ServiceID value from web.config" />
    <add key="ServiceKey" value="ServiceKey value from web.config" />
  </appSettings>

  <connectionStrings configBuilders="MyEnvironment">
    <add name="default" connectionString="Data Source=web.config/mydb.db" />
  </connectionStrings>
```

The following code reads the `<appSettings/>` and `<connectionStrings/>` shown in the preceding *web.config* file:

```
using System;
using System.Configuration;
using System.Web.UI;

namespace MyConfigBuilders
{
    public partial class About : Page
    {
        public string ServiceID { get; set; }
        public string ServiceKey { get; set; }
        public string ConString { get; set; }

        protected void Page_Load(object sender, EventArgs e)
        {
            ServiceID = ConfigurationManager.AppSettings["ServiceID"];
            ServiceKey = ConfigurationManager.AppSettings["ServiceKey"];
            ConString = ConfigurationManager.ConnectionStrings["default"]
                                                ?.ConnectionString;
        }
    }
}
```

The preceding code will set the property values to:

- The values in the *web.config* file if the keys are not set in environment variables.
- The values of the environment variable, if set.

For example, `ServiceID` will contain:

- "ServiceID value from web.config", if the environment variable `ServiceID` is not set.

- The value of the `ServiceID` environment variable, if set.

The following image shows the `<appSettings/>` keys/values from the preceding *web.config* file set in the environment editor:

Note: You might need to exit and restart Visual Studio to see changes in environment variables.

Prefix handling

Key prefixes can simplify setting keys because:

- The .NET Framework configuration is complex and nested.
- External key/value sources are commonly basic and flat by nature. For example, environment variables are not nested.

Use any of the following approaches to inject both `<appSettings/>` and `<connectionStrings/>` into the configuration via environment variables:

- With the `EnvironmentConfigBuilder` in the default `Strict` mode and the appropriate key names in the configuration file. The preceding code and markup takes this approach. Using this approach you can **not** have identically named keys in both `<appSettings/>` and `<connectionStrings/>`.
- Use two `EnvironmentConfigBuilder`s in `Greedy` mode with distinct prefixes and `stripPrefix`. With this approach, the app can read `<appSettings/>` and `<connectionStrings/>` without needing to update the configuration file. The next section, stripPrefix, shows how to do this.
- Use two `EnvironmentConfigBuilder`s in `Greedy` mode with distinct prefixes. With this approach you can't have duplicate key names as key names must differ by prefix. For example:

```
<configuration>

  <configSections>
    <section name="configBuilders"
             type="System.Configuration.ConfigurationBuildersSection,
             System.Configuration, Version=4.0.0.0, Culture=neutral,
             PublicKeyToken=b03f5f7f11d50a3a"
             restartOnExternalChanges="false" requirePermission="false" />
  </configSections>

  <configBuilders>
    <builders>
      <add name="AS_Environment" mode="Greedy" prefix="AppSetting_"
           type="Microsoft.Configuration.ConfigurationBuilders.EnvironmentConfigBuilder,
           Microsoft.Configuration.ConfigurationBuilders.Environment" />
      <add name="CS_Environment" mode="Greedy" prefix="ConnStr_"
           type="Microsoft.Configuration.ConfigurationBuilders.EnvironmentConfigBuilder,
           Microsoft.Configuration.ConfigurationBuilders.Environment" />
    </builders>
  </configBuilders>

  <appSettings configBuilders="AS_Environment">
    <add key="AppSetting_ServiceID" value="ServiceID value from web.config" />
    <add key="AppSetting_default" value="AppSetting_default value from web.config" />
  </appSettings>

  <connectionStrings configBuilders="CS_Environment">
    <add name="ConnStr_default" connectionString="Data Source=web.config/mydb.db" />
  </connectionStrings>
```

With the preceding markup, the same flat key/value source can be used to populate configuration for two different sections.

The following image shows the `<appSettings/>` and `<connectionStrings/>` keys/values from the preceding *web.config* file set in the environment editor:

The following code reads the `<appSettings/>` and `<connectionStrings/>` keys/values contained in the preceding *web.config* file:

```
public partial class Contact : Page
{
    public string ServiceID { get; set; }
    public string AppSetting_default { get; set; }
    public string ConString { get; set; }

    protected void Page_Load(object sender, EventArgs e)
    {
        ServiceID = ConfigurationManager.AppSettings["AppSetting_ServiceID"];
        AppSetting_default = ConfigurationManager.AppSettings["AppSetting_default"];
        ConString = ConfigurationManager.ConnectionStrings["ConnStr_default"]
                                    ?.ConnectionString;
    }
}
```

The preceding code will set the property values to:

- The values in the *web.config* file if the keys are not set in environment variables.
- The values of the environment variable, if set.

For example, using the previous *web.config* file, the keys/values in the previous environment editor image, and the previous code, the following values are set:

KEY	VALUE
AppSetting_ServiceID	AppSetting_ServiceID from env variables
AppSetting_default	AppSetting_default value from env
ConnStr_default	ConnStr_default val from env

stripPrefix

`stripPrefix`: boolean, defaults to `false`.

The preceding XML markup separates app settings from connection strings but requires all the keys in the *web.config* file to use the specified prefix. For example, the prefix `AppSetting` must be added to the `ServiceID` key ("AppSetting_ServiceID"). With `stripPrefix`, the prefix is not used in the *web.config* file. The prefix is required in the configuration builder source (for example, in the environment.) We anticipate most developers will use `stripPrefix`.

Applications typically strip off the prefix. The following *web.config* strips the prefix:

```
<configuration>

  <configSections>
    <section name="configBuilders"
             type="System.Configuration.ConfigurationBuildersSection,
             System.Configuration, Version=4.0.0.0, Culture=neutral,
             PublicKeyToken=b03f5f7f11d50a3a"
             restartOnExternalChanges="false" requirePermission="false" />
  </configSections>

  <configBuilders>
    <builders>
      <add name="AS_Environment" mode="Greedy" prefix="AppSetting_"
           stripPrefix="true"
           type="Microsoft.Configuration.ConfigurationBuilders.EnvironmentConfigBuilder,
           Microsoft.Configuration.ConfigurationBuilders.Environment,
           Version=1.0.0.0, Culture=neutral" />
      <add name="CS_Environment" mode="Greedy" prefix="ConnStr_"
           stripPrefix="true"
            type="Microsoft.Configuration.ConfigurationBuilders.EnvironmentConfigBuilder,
           Microsoft.Configuration.ConfigurationBuilders.Environment,
           Version=1.0.0.0, Culture=neutral" />
    </builders>
  </configBuilders>

  <appSettings configBuilders="AS_Environment">
    <add key="ServiceID" value="ServiceID value from web.config" />
    <add key="default" value="AppSetting_default value from web.config" />
  </appSettings>

  <connectionStrings configBuilders="CS_Environment">
    <add name="default" connectionString="Data Source=web.config/mydb.db" />
  </connectionStrings>
```

In the preceding *web.config* file, the `default` key is in both the `<appSettings/>` and `<connectionStrings/>`.

The following image shows the `<appSettings/>` and `<connectionStrings/>` keys/values from the preceding *web.config* file set in the environment editor:

The following code reads the `<appSettings/>` and `<connectionStrings/>` keys/values contained in the preceding *web.config* file:

```
public partial class About2 : Page
{
    public string ServiceID { get; set; }
    public string AppSetting_default { get; set; }
    public string ConString { get; set; }

    protected void Page_Load(object sender, EventArgs e)
    {
        ServiceID = ConfigurationManager.AppSettings["ServiceID"];
        AppSetting_default = ConfigurationManager.AppSettings["default"];
        ConString = ConfigurationManager.ConnectionStrings["default"]
                                        ?.ConnectionString;
    }
}
```

The preceding code will set the property values to:

- The values in the *web.config* file if the keys are not set in environment variables.
- The values of the environment variable, if set.

For example, using the previous *web.config* file, the keys/values in the previous environment editor image, and the previous code, the following values are set:

KEY	VALUE
ServiceID	AppSetting_ServiceID from env variables
default	AppSetting_default value from env
default	ConnStr_default val from env

tokenPattern

`tokenPattern`: String, defaults to `@"\$\{(\w+)\}"`

The `Expand` behavior of the builders searches the raw XML for tokens that look like `${token}`. Searching is done with the default regular expression `@"\$\{(\w+)\}"`. The set of characters that matches `\w` is more strict than XML and many configuration sources allow. Use `tokenPattern` when more characters than `@"\$\{(\w+)\}"` are required in the token name.

`tokenPattern`: String:

- Allows developers to change the regex that is used for token matching.
- No validation is done to make sure it is a well-formed, non-dangerous regex.
- It must contain a capture group. The entire regex must match the entire token. The first capture must be the token name to look up in the configuration source.

Configuration builders in Microsoft.Configuration.ConfigurationBuilders

EnvironmentConfigBuilder

```
<add name="Environment"
    [mode|prefix|stripPrefix|tokenPattern]
    type="Microsoft.Configuration.ConfigurationBuilders.EnvironmentConfigBuilder,
    Microsoft.Configuration.ConfigurationBuilders.Environment" />
```

The EnvironmentConfigBuilder:

- Is the simplest of the configuration builders.
- Reads values from the environment.
- Does not have any additional configuration options.
- The `name` attribute value is arbitrary.

Note: In a Windows container environment, variables set at run time are only injected into the EntryPoint process environment. Apps that run as a service or a non-EntryPoint process do not pick up these variables unless they are otherwise injected through a mechanism in the container. For IIS/ASP.NET-based containers, the current version of ServiceMonitor.exe handles this in the *DefaultAppPool* only. Other Windows-based container variants may need to develop their own injection mechanism for non-EntryPoint processes.

UserSecretsConfigBuilder

> **WARNING**
>
> Never store passwords, sensitive connection strings, or other sensitive data in source code. Production secrets should not be used for development or test.

```
<add name="UserSecrets"
    [mode|prefix|stripPrefix|tokenPattern]
    (userSecretsId="{secret string, typically a GUID}" | userSecretsFile="~\secrets.file")
    [optional="true"]
    type="Microsoft.Configuration.ConfigurationBuilders.UserSecretsConfigBuilder,
    Microsoft.Configuration.ConfigurationBuilders.UserSecrets" />
```

This configuration builder provides a feature similar to ASP.NET Core Secret Manager.

The UserSecretsConfigBuilder can be used in .NET Framework projects, but a secrets file must be specified. Alternatively, you can define the `UserSecretsId` property in the project file and create the raw secrets file in the correct location for reading. To keep external dependencies out of your project, the secret file is XML formatted. The XML formatting is an implementation detail, and the format should not be relied upon. If you need to share a *secrets.json* file with .NET Core projects, consider using the SimpleJsonConfigBuilder. The `SimpleJsonConfigBuilder` format for .NET Core should also be considered an implementation detail subject to change.

Configuration attributes for `UserSecretsConfigBuilder`:

- `userSecretsId` - This is the preferred method for identifying an XML secrets file. It works similar to .NET Core, which uses a `UserSecretsId` project property to store this identifier. The string must be unique, it doesn't need to be a GUID. With this attribute, the `UserSecretsConfigBuilder` look in a well-known local location (`%APPDATA%\Microsoft\UserSecrets\<UserSecrets Id>\secrets.xml`) for a secrets file belonging to this identifier.
- `userSecretsFile` - An optional attribute specifying the file containing the secrets. The `~` character can be used at the start to reference the application root. Either this attribute or the `userSecretsId` attribute is required. If both are specified, `userSecretsFile` takes precedence.
- `optional`: boolean, default value `true` - Prevents an exception if the secrets file cannot be found.
- The `name` attribute value is arbitrary.

The secrets file has the following format:

```
<?xml version="1.0" encoding="utf-8" ?>
<root>
  <secrets ver="1.0">
    <secret name="secret key name" value="secret value" />
  </secrets>
</root>
```

AzureKeyVaultConfigBuilder

```
<add name="AzureKeyVault"
    [mode|prefix|stripPrefix|tokenPattern]
    (vaultName="MyVaultName" |
     uri="https:/MyVaultName.vault.azure.net")
    [connectionString="connection string"]
    [version="secrets version"]
    [preloadSecretNames="true"]
    type="Microsoft.Configuration.ConfigurationBuilders.AzureKeyVaultConfigBuilder,
    Microsoft.Configuration.ConfigurationBuilders.Azure" />
```

The AzureKeyVaultConfigBuilder reads values stored in the Azure Key Vault.

`vaultName` is required (either the name of the vault or a URI to the vault). The other attributes allow control about which vault to connect to, but are only necessary if the application is not running in an environment that works with `Microsoft.Azure.Services.AppAuthentication`. The Azure Services Authentication library is used to automatically pick up connection information from the execution environment if possible. You can override automatically pick up of connection information by providing a connection string.

- `vaultName` - Required if `uri` in not provided. Specifies the name of the vault in your Azure subscription from which to read key/value pairs.
- `connectionString` - A connection string usable by AzureServiceTokenProvider
- `uri` - Connects to other Key Vault providers with the specified `uri` value. If not specified, Azure (`vaultName`) is the vault provider.
- `version` - Azure Key Vault provides a versioning feature for secrets. If `version` is specified, the builder only retrieves secrets matching this version.
- `preloadSecretNames` - By default, this builder querys **all** key names in the key vault when it is initialized. To prevent reading all key values, set this attribute to `false`. Setting this to `false` reads secrets one at a time. Reading secrets one at a time can useful if the vault allows "Get" access but not "List" access. **Note:** When using `Greedy` mode, `preloadSecretNames` must be `true` (the default.)

KeyPerFileConfigBuilder

```
<add name="KeyPerFile"
    [mode|prefix|stripPrefix|tokenPattern]
    (directoryPath="PathToSourceDirectory")
    [ignorePrefix="ignore."]
    [keyDelimiter=":"]
    [optional="false"]
    type="Microsoft.Configuration.ConfigurationBuilders.KeyPerFileConfigBuilder,
    Microsoft.Configuration.ConfigurationBuilders.KeyPerFile" />
```

KeyPerFileConfigBuilder is a basic configuration builder that uses a directory's files as a source of values. A file's name is the key, and the contents are the value. This configuration builder can be useful when running in an orchestrated container environment. Systems like Docker Swarm and Kubernetes provide `secrets` to their orchestrated windows containers in this key-per-file manner.

Attribute details:

- `directoryPath` - Required. Specifies a path to look in for values. Docker for Windows secrets are stored in the *C:\ProgramData\Docker\secrets* directory by default.
- `ignorePrefix` - Files that start with this prefix are excluded. Defaults to "ignore.".
- `keyDelimiter` - Default value is `null`. If specified, the configuration builder traverses multiple levels of the directory, building up key names with this delimiter. If this value is `null`, the configuration builder only looks at the top level of the directory.
- `optional` - Default value is `false`. Specifies whether the configuration builder should cause errors if the source directory doesn't exist.

SimpleJsonConfigBuilder

> **WARNING**
> Never store passwords, sensitive connection strings, or other sensitive data in source code. Production secrets should not be used for development or test.

```
<add name="SimpleJson"
    [mode|prefix|stripPrefix|tokenPattern]
    jsonFile="~\config.json"
    [optional="true"]
    [jsonMode="(Flat|Sectional)"]
    type="Microsoft.Configuration.ConfigurationBuilders.SimpleJsonConfigBuilder,
    Microsoft.Configuration.ConfigurationBuilders.Json" />
```

.NET Core projects frequently use JSON files for configuration. The SimpleJsonConfigBuilder builder allows .NET

Core JSON files to be used in the .NET Framework. This configuration builder is provides a basic mapping from a flat key/value source into specific key/value areas of .NET Framework configuration. This configuration builder does **not** provide for hierarchical configurations. The JSON backing file is similar to a dictionary, not a complex hierarchical object. A multi-level hierarchical file can be used. This provider `flatten`s the depth by appending the property name at each level using `:` as a delimiter.

Attribute details:

- `jsonFile` - Required. Specifies the JSON file to read from. The `~` character can be used at the start to reference the app root.
- `optional` - Boolean, default value is `true`. Prevents throwing exceptions if the JSON file cannot be found.
- `jsonMode` - `[Flat|Sectional]`. `Flat` is the default. When `jsonMode` is `Flat`, the JSON file is a single flat key/value source. The `EnvironmentConfigBuilder` and `AzureKeyVaultConfigBuilder` are also single flat key/value sources. When the `SimpleJsonConfigBuilder` is configured in `Sectional` mode:
  - The JSON file is conceptually divided just at the top level into multiple dictionaries.
  - Each of the dictionaries is only applied to the configuration section that matches the top-level property name attached to them. For example:

```
{
    "appSettings" : {
        "setting1" : "value1",
        "setting2" : "value2",
        "complex" : {
            "setting1" : "complex:value1",
            "setting2" : "complex:value2",
        }
    }
}
```

Configuration builders order

See ConfigurationBuilders Order of Execution in the aspnet/MicrosoftConfigurationBuilders GitHub repository.

Implementing a custom key/value configuration builder

If the configuration builders don't meet your needs, you can write a custom one. The `KeyValueConfigBuilder` base class handles substitution modes and most prefix concerns. An implementing project need only:

- Inherit from the base class and implement a basic source of key/value pairs through the `GetValue` and `GetAllValues`:
- Add the Microsoft.Configuration.ConfigurationBuilders.Base to the project.

```
using Microsoft.Configuration.ConfigurationBuilders;
using System.Collections.Generic;

public class MyCustomConfigBuilder : KeyValueConfigBuilder
{
    public override string GetValue(string key)
    {
        // Key lookup should be case-insensitive, because most key/value collections in
        // .NET Framework config sections are case-insensitive.
        return "Value for given key, or null.";
    }

    public override ICollection<KeyValuePair<string, string>> GetAllValues(string prefix)
    {
        // Populate the return collection.
        return new Dictionary<string, string>() { { "one", "1" }, { "two", "2" } };
    }
}
```

The `KeyValueConfigBuilder` base class provides much of the work and consistent behavior across key/value configuration builders.

Introduction to SignalR

9/16/2020 • 8 minutes to read • Edit Online

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This article describes what SignalR is, and some of the solutions it was designed to create.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

What is SignalR?

ASP.NET SignalR is a library for ASP.NET developers that simplifies the process of adding real-time web functionality to applications. Real-time web functionality is the ability to have server code push content to connected clients instantly as it becomes available, rather than having the server wait for a client to request new data.

SignalR can be used to add any sort of "real-time" web functionality to your ASP.NET application. While chat is often used as an example, you can do a whole lot more. Any time a user refreshes a web page to see new data, or the page implements long polling to retrieve new data, it is a candidate for using SignalR. Examples include dashboards and monitoring applications, collaborative applications (such as simultaneous editing of documents), job progress updates, and real-time forms.

SignalR also enables completely new types of web applications that require high frequency updates from the server, for example, real-time gaming.

SignalR provides a simple API for creating server-to-client remote procedure calls (RPC) that call JavaScript functions in client browsers (and other client platforms) from server-side .NET code. SignalR also includes API for connection management (for instance, connect and disconnect events), and grouping connections.

SignalR handles connection management automatically, and lets you broadcast messages to all connected clients simultaneously, like a chat room. You can also send messages to specific clients. The connection between the client and server is persistent, unlike a classic HTTP connection, which is re-established for each communication.

SignalR supports "server push" functionality, in which server code can call out to client code in the browser using Remote Procedure Calls (RPC), rather than the request-response model common on the web today.

SignalR applications can scale out to thousands of clients using built-in, and third-party scale-out providers.

Built-in providers include:

- Service Bus
- SQL Server
- Redis

Third-party providers include:

- NCache.

SignalR is open-source, accessible through GitHub.

SignalR and WebSocket

SignalR uses the new WebSocket transport where available and falls back to older transports where necessary. While you could certainly write your app using WebSocket directly, using SignalR means that a lot of the extra functionality you would need to implement is already done for you. Most importantly, this means that you can code your app to take advantage of WebSocket without having to worry about creating a separate code path for older clients. SignalR also shields you from having to worry about updates to WebSocket, since SignalR is updated to support changes in the underlying transport, providing your application a consistent interface across versions of WebSocket.

Transports and fallbacks

SignalR is an abstraction over some of the transports that are required to do real-time work between client and server. SignalR first attempts to establish a WebSocket connection if possible. WebSocket is the optimal transport for SignalR because it has:

- The most efficient use of server memory.
- The lowest latency.
- The most underlying features, such as full duplex communication between client and server.
- The most stringent requirements, WebSocket requires the server:
  - Run on Windows Server 2012 or Windows 8.
  - .NET Framework 4.5.

If these requirements are not met, SignalR attempts to use other transports to make its connections.

HTML 5 transports

These transports depend on support for HTML 5. If the client browser does not support the HTML 5 standard, older transports will be used.

- **WebSocket** (if both the server and browser indicate they can support Websocket). WebSocket is the only transport that establishes a true persistent, two-way connection between client and server. However, WebSocket also has the most stringent requirements; it is fully supported only in the latest versions of Microsoft Internet Explorer, Google Chrome, and Mozilla Firefox, and only has a partial implementation in other browsers such as Opera and Safari.
- **Server Sent Events**, also known as EventSource (if the browser supports Server Sent Events, which is basically all browsers except Internet Explorer.)

Comet transports

The following transports are based on the Comet web application model, in which a browser or other client maintains a long-held HTTP request, which the server can use to push data to the client without the client specifically requesting it.

- **Forever Frame** (for Internet Explorer only). Forever Frame creates a hidden IFrame which makes a request to an endpoint on the server that does not complete. The server then continually sends script to the client which is immediately executed, providing a one-way realtime connection from server to client. The connection from client to server uses a separate connection from the server to client connection, and like a standard HTTP request, a new connection is created for each piece of data that needs to be sent.
- **Ajax long polling**. Long polling does not create a persistent connection, but instead polls the server with a request that stays open until the server responds, at which point the connection closes, and a new connection is requested immediately. This may introduce some latency while the connection resets.

For more information on what transports are supported under which configurations, see Supported Platforms.

Transport selection process

The following list shows the steps that SignalR uses to decide which transport to use.

1. If the browser is Internet Explorer 8 or earlier, Long Polling is used.

2. If JSONP is configured (that is, the `jsonp` parameter is set to `true` when the connection is started), Long Polling is used.

3. If a cross-domain connection is being made (that is, if the SignalR endpoint is not in the same domain as the hosting page), then WebSocket will be used if the following criteria are met:

   - The client supports CORS (Cross-Origin Resource Sharing). For details on which clients support CORS, see CORS at caniuse.com.

- The client supports WebSocket
- The server supports WebSocket

  If any of these criteria are not met, Long Polling will be used. For more information on cross-domain connections, see How to establish a cross-domain connection.

4. If JSONP is not configured and the connection is not cross-domain, WebSocket will be used if both the client and server support it.
5. If either the client or server do not support WebSocket, Server Sent Events is used if it is available.
6. If Server Sent Events is not available, Forever Frame is attempted.
7. If Forever Frame fails, Long Polling is used.

Monitoring transports

You can determine what transport your application is using by enabling logging on your hub, and opening the console window in your browser.

To enable logging for your hub's events in a browser, add the following command to your client application:

```
$.connection.hub.logging = true;
```

- In Internet Explorer, open the developer tools by pressing F12, and click the Console tab.

- In Chrome, open the console by pressing Ctrl+Shift+J.

With the console open and logging enabled, you'll be able to see which transport is being used by SignalR.

Specifying a transport

Negotiating a transport takes a certain amount of time and client/server resources. If the client capabilities are known, then a transport can be specified when the client connection is started. The following code snippet demonstrates starting a connection using the Ajax Long Polling transport, as would be used if it was known that the client did not support any other protocol:

```
connection.start({ transport: 'longPolling' });
```

You can specify a fallback order if you want a client to try specific transports in order. The following code snippet demonstrates trying WebSocket, and failing that, going directly to Long Polling.

```
connection.start({ transport: ['webSockets','longPolling'] });
```

The string constants for specifying transports are defined as follows:

- `webSockets`
- `foreverFrame`
- `serverSentEvents`
- `longPolling`

Connections and Hubs

The SignalR API contains two models for communicating between clients and servers: Persistent Connections and Hubs.

A Connection represents a simple endpoint for sending single-recipient, grouped, or broadcast messages. The Persistent Connection API (represented in .NET code by the PersistentConnection class) gives the developer direct access to the low-level communication protocol that SignalR exposes. Using the Connections communication model will be familiar to developers who have used connection-based APIs such as Windows Communication Foundation.

A Hub is a more high-level pipeline built upon the Connection API that allows your client and server to call methods on each other directly. SignalR handles the dispatching across machine boundaries as if by magic, allowing clients to call methods on the server as easily as local methods, and vice versa. Using the Hubs communication model will be familiar to developers who have used remote invocation APIs such as .NET Remoting. Using a Hub also allows you to pass strongly typed parameters to methods, enabling model binding.

Architecture diagram

The following diagram shows the relationship between Hubs, Persistent Connections, and the underlying technologies used for transports.

How Hubs work

When server-side code calls a method on the client, a packet is sent across the active transport that contains the name and parameters of the method to be called (when an object is sent as a method parameter, it is serialized using JSON). The client then matches the method name to methods defined in client-side code. If there is a match, the client method will be executed using the deserialized parameter data.

The method call can be monitored using tools like Fiddler. The following image shows a method call sent from a SignalR server to a web browser client in the Logs pane of Fiddler. The method call is being sent from a hub called `MoveShapeHub`, and the method being invoked is called `updateShape`.

```

22 48 22 3A 22 4D 6F 76 65 53 68 61 70 65 48 75  "H":"MoveShapeHu
62 22 2C 22 4D 22 3A 22 75 70 64 61 74 65 53 68  b","M":"updateSh
61 70 65 22 2C 22 41 22 3A 5B 7B 22 6C 65 66 74  ape","A":[{"left
22 3A 35 30 31 2E 30 2C 22 74 6F 70 22 3A 33 30  ":501.0,"top":30
32 2E 30 7D 5D 7D 5D 7D                          2.0}]}]}
```

In this example, the hub name is identified with the `H` parameter; the method name is identified with the `M` parameter, and the data being sent to the method is identified with the `A` parameter. The application that generated this message is created in the High-Frequency Realtime tutorial.

Choosing a communication model

Most applications should use the Hubs API. The Connections API could be used in the following circumstances:

- The format of the actual message sent needs to be specified.
- The developer prefers to work with a messaging and dispatching model rather than a remote invocation model.
- An existing application that uses a messaging model is being ported to use SignalR.

Supported Platforms

by Patrick Fletcher

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This article describes what clients and servers are supported by SignalR.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

SignalR is supported under a variety of server and client configurations. In addition, each transport option has a set of requirements of its own; if the system requirements for a transport are not available, SignalR will gracefully failover to other transports. For more information on the transports that SignalR supports, see Transports and Fallbacks.

Server system requirements

The SignalR server component can be hosted on a variety of server configurations. This section describes the supported versions of operating systems, .NET framework, Internet Information Server, and other components.

Supported server operating systems

The SignalR server component can be hosted in the following server or client operating systems. Note that for SignalR to use WebSockets, Windows Server 2012, Windows Server 2016, or Windows 8 is required (WebSocket can be used on Windows Azure Web Sites, as long as the site's .NET framework version is set to 4.5, and Web Sockets is enabled in the site's Configuration page).

- Windows Server 2016
- Windows Server 2012
- Windows Server 2008 r2
- Windows 10
- Windows 8
- Windows 7
- Windows Azure

Supported server .NET Framework version

SignalR 2 is only supported on .NET Framework 4.5. See the Recommended Updates section for updates that enhance reliability, compatibility, stability, and performance.

Supported server IIS versions

When SignalR is hosted in IIS, the following versions are supported. Note that if a client operating system is used, such as for development (Windows 8 or Windows 7), full versions of IIS or Cassini should not be used, since there will be a limit of 10 simultaneous connections imposed, which will be reached very quickly since connections are

transient, frequently re-established, and are not disposed immediately upon no longer being used. IIS Express should be used on client operating systems.

Also note that for SignalR to use WebSocket, IIS 8 or IIS 8 Express must be used, the server must be using Windows 8, Windows Server 2012, or later, and WebSocket must be enabled in IIS. For information on how to enable WebSocket in IIS, see IIS 8.0 WebSocket Protocol Support.

- IIS 8 or IIS 8 Express.
- IIS 7 and 7.5. Support for extensionless URLs is required.
- IIS must be running in integrated mode; classic mode is not supported. Message delays of up to 30 seconds may be experienced if IIS is run in classic mode using the Server-Sent Events transport.
- The hosting application must be running in full trust mode.

Client system requirements

SignalR can be used in a variety of client platforms. This section describes the system requirements for using SignalR in web browsers, Windows desktop applications, Silverlight applications, and mobile devices.

Web browsers

SignalR can be used in a variety of web browsers, but typically, only the latest two versions are supported.

Applications that use SignalR in browsers must use jQuery version 1.6.4 or major later versions (such as 1.7.2, 1.8.2, or 1.9.1).

SignalR can be used in the following browsers:

- Microsoft Internet Explorer versions 8, 9, 10, and 11. Modern, Desktop, and Mobile versions are supported.
- Mozilla Firefox: current version - 1, both Windows and Mac versions.
- Google Chrome: current version - 1, both Windows and Mac versions.
- Safari: current version - 1, both Mac and iOS versions.
- Opera: current version - 1, Windows only.
- Android browser

In addition to requiring certain browsers, the various transports that SignalR uses have requirements of their own. The following transports are supported under the following configurations:

Web Browser Transport Requirements

TRANSPORT	INTERNET EXPLORER	CHROME (WINDOWS OR IOS)	FIREFOX	SAFARI (OSX OR IOS)	ANDROID
WebSockets	10+	current - 1	current - 1	current - 1	N/A
Server-Sent Events	N/A	current - 1	current - 1	current - 1	N/A
ForeverFrame	8+	N/A	N/A	N/A	4.1
Long Polling	8+	current - 1	current - 1	current - 1	4.1

*: 6+ required for full functionality.

Unsupported Browsers

While SignalR *may* run without major issues in older browser versions, we do not actively test SignalR in them and generally do not fix bugs that may appear in them.

Windows Desktop and Silverlight Applications

In addition to running in a web browser, SignalR can be hosted in standalone Windows client or Silverlight applications. Windows Desktop and Silverlight SignalR applications have the following system requirements.

- Applications using .NET 4 are supported on Windows XP SP3 or later.
- Applications using .NET Framework 4.5 are supported on Windows Vista or later.

In addition to operating system and .NET framework requirements, the transports available to SignalR have requirements of their own. The following transports are supported under the following configurations:

Windows Desktop and Silverlight Transport Requirements

TRANSPORT	.NET APPLICATION	SILVERLIGHT
Web Sockets	Windows 8+ and .NET 4.5+	N/A
Forever Frame	N/A	N/A
Server-Sent Events	.NET 4+	5+
Long Polling	.NET 4+	5+

Windows Store and Windows Phone Applications

SignalR can be used in Windows Store applications and Windows Phone 8 applications. The following transports are supported under the following configurations:

Windows Store and Windows Phone Transport Requirements

TRANSPORT	WINDOWS STORE/ .NET	WINDOWS STORE/ JAVASCRIPT	WINDOWS PHONE/ IE	WINDOWS PHONE/ .NET
WebSockets	N/A	Win8+	8+	N/A
Forever Frame	N/A	Win8+	7.5+	N/A
Server-Sent Events	Win8+	N/A	N/A	8+
Long Polling	Win8+	Win8+	7.5+	8+

Recommended Updates

The following updates are recommended for SignalR servers:

- An update for .NET Framework 4.5 is available here.
- Microsoft will periodically release QFEs for ASP.NET. These should be applied as available.

Tutorial: Real-time chat with SignalR 2

2/20/2020 • 6 minutes to read • Edit Online

This tutorial shows you how to use SignalR to create a real-time chat application. You add SignalR to an empty ASP.NET web application and create an HTML page to send and display messages.

In this tutorial, you:

- Set up the project
- Run the sample
- Examine the code

> **WARNING**
>
> This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

Prerequisites

- Visual Studio 2017 with the **ASP.NET and web development** workload.

Set up the Project

This section shows how to use Visual Studio 2017 and SignalR 2 to create an empty ASP.NET web application, add SignalR, and create the chat application.

1. In Visual Studio, create an ASP.NET Web Application.

2. In the **New ASP.NET Project - SignalRChat** window, leave **Empty** selected and select **OK**.

3. In **Solution Explorer**, right-click the project and select **Add** > **New Item**.
4. In **Add New Item - SignalRChat**, select **Installed** > **Visual C#** > **Web** > **SignalR** and then select **SignalR Hub Class (v2)**.
5. Name the class *ChatHub* and add it to the project.

   This step creates the *ChatHub.cs* class file and adds a set of script files and assembly references that support SignalR to the project.
6. Replace the code in the new *ChatHub.cs* class file with this code:

```
using System;
using System.Web;
using Microsoft.AspNet.SignalR;
namespace SignalRChat
{
    public class ChatHub : Hub
    {
        public void Send(string name, string message)
        {
            // Call the broadcastMessage method to update clients.
            Clients.All.broadcastMessage(name, message);
        }
    }
}
```

7. In **Solution Explorer**, right-click the project and select **Add** > **New Item**.
8. In **Add New Item - SignalRChat** select **Installed** > **Visual C#** > **Web** and then select **OWIN Startup Class**.
9. Name the class *Startup* and add it to the project.
10. Replace the default code in *Startup* class with this code:

```
using Microsoft.Owin;
using Owin;
[assembly: OwinStartup(typeof(SignalRChat.Startup))]
namespace SignalRChat
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            // Any connection or hub wire up and configuration should go here
            app.MapSignalR();
        }
    }
}
```

11. In **Solution Explorer**, right-click the project and select **Add** > **HTML Page**.
12. Name the new page *index* and select **OK**.
13. In **Solution Explorer**, right-click the HTML page you created and select **Set as Start Page**.
14. Replace the default code in the HTML page with this code:

```
<!DOCTYPE html>
<html>
<head>
    <title>SignalR Simple Chat</title>
    <style type="text/css">
        .container {
            background-color: #99CCFF;
            border: thick solid #808080;
            padding: 20px;
            margin: 20px;
        }
    </style>
</head>
<body>
    <div class="container">
        <input type="text" id="message" />
        <input type="button" id="sendmessage" value="Send" />
        <input type="hidden" id="displayname" />
        <ul id="discussion">
        </ul>
    </div>
    <!--Script references. -->
    <!--Reference the jQuery library. -->
    <script src="Scripts/jquery-3.1.1.min.js" ></script>
    <!--Reference the SignalR library. -->
    <script src="Scripts/jquery.signalR-2.2.1.min.js"></script>
    <!--Reference the autogenerated SignalR hub script. -->
    <script src="signalr/hubs"></script>
    <!--Add script to update the page and send messages.-->
    <script type="text/javascript">
        $(function () {
            // Declare a proxy to reference the hub.
            var chat = $.connection.chatHub;
            // Create a function that the hub can call to broadcast messages.
            chat.client.broadcastMessage = function (name, message) {
                // Html encode display name and message.
                var encodedName = $('<div />').text(name).html();
                var encodedMsg = $('<div />').text(message).html();
                // Add the message to the page.
                $('#discussion').append('<li><strong>' + encodedName
                    + '</strong>:  ' + encodedMsg + '</li>');
            };
            // Get the user name and store it to prepend to messages.
            $('#displayname').val(prompt('Enter your name:', ''));
            // Set initial focus to message input box.
            $('#message').focus();
            // Start the connection.
            $.connection.hub.start().done(function () {
                $('#sendmessage').click(function () {
                    // Call the Send method on the hub.
                    chat.server.send($('#displayname').val(), $('#message').val());
                    // Clear text box and reset focus for next comment.
                    $('#message').val('').focus();
                });
            });
        });
    </script>
</body>
</html>
```

15. In **Solution Explorer**, expand **Scripts**.

    Script libraries for jQuery and SignalR are visible in the project.

> **IMPORTANT**
>
> The package manager may have installed a later version of the SignalR scripts.

16. Check that the script references in the code block correspond to the versions of the script files in the project.

    Script references from the original code block:

    ```
    <!--Script references. -->
    <!--Reference the jQuery library. -->
    <script src="Scripts/jquery-3.1.1.min.js" ></script>
    <!--Reference the SignalR library. -->
    <script src="Scripts/jquery.signalR-2.2.1.min.js"></script>
    ```

17. If they don't match, update the *.html* file.

18. From the menu bar, select **File** > **Save All**.

Run the Sample

1. In the toolbar, turn on **Script Debugging** and then select the play button to run the sample in Debug mode.

2. When the browser opens, enter a name for your chat identity.

3. Copy the URL from the browser, open two other browsers, and paste the URLs into the address bars.

4. In each browser, enter a unique name.

5. Now, add a comment and select **Send**. Repeat that in the other browsers. The comments appear in real-time.

> **NOTE**
>
> This simple chat application does not maintain the discussion context on the server. The hub broadcasts comments to all current users. Users who join the chat later will see messages added from the time they join.

See how the chat application runs in three different browsers. When Tom, Anand, and Susan send messages, all browsers update in real time:

6. In **Solution Explorer**, inspect the **Script Documents** node for the running application. There's a script file named *hubs* that the SignalR library generates at runtime. This file manages the communication between jQuery script and server-side code.

Examine the Code

The SignalRChat application demonstrates two basic SignalR development tasks. It shows you how to create a hub. The server uses that hub as the main coordination object. The hub uses the SignalR jQuery library to send

and receive messages.

SignalR Hubs in the ChatHub.cs

In the code sample above, the `ChatHub` class derives from the `Microsoft.AspNet.SignalR.Hub` class. Deriving from the `Hub` class is a useful way to build a SignalR application. You can create public methods on your hub class and then use those methods by calling them from scripts in a web page.

In the chat code, clients call the `ChatHub.Send` method to send a new message. The hub then sends the message to all clients by calling `Clients.All.broadcastMessage`.

The `Send` method demonstrates several hub concepts:

- Declare public methods on a hub so that clients can call them.
- Use the `Microsoft.AspNet.SignalR.Hub.Clients` dynamic property to communicate with all clients connected to this hub.
- Call a function on the client (like the `broadcastMessage` function) to update clients.

```
public class ChatHub : Hub
{
    public void Send(string name, string message)
    {
        // Call the broadcastMessage method to update clients.
        Clients.All.broadcastMessage(name, message);
    }
}
```

SignalR and jQuery in the index.html

The *index.html* page in the code sample shows how to use the SignalR jQuery library to communicate with a SignalR hub. The code carries out many important tasks. It declares a proxy to reference the hub, declares a function that the server can call to push content to clients, and it starts a connection to send messages to the hub.

```
var chat = $.connection.chatHub;
```

> **NOTE**
>
> In JavaScript the reference to the server class and its members has to be camelCase. The code sample references the C# *ChatHub* class in JavaScript as `chatHub`.

In this code block, you create a callback function in the script.

```
chat.client.broadcastMessage = function (name, message) {
        // Html encode display name and message.
        var encodedName = $('<div />').text(name).html();
        var encodedMsg = $('<div />').text(message).html();
        // Add the message to the page.
        $('#discussion').append('<li><strong>' + encodedName
            + '</strong>:  ' + encodedMsg + '</li>');
    };
```

The hub class on the server calls this function to push content updates to each client. The two lines that HTML-encode the content before displaying it are optional and show a good way to prevent script injection.

This code opens a connection with the hub.

```
$.connection.hub.start().done(function () {
        $('#sendmessage').click(function () {
            // Call the Send method on the hub.
            chat.server.send($('#displayname').val(), $('#message').val());
            // Clear text box and reset focus for next comment.
            $('#message').val('').focus();
        });
    });
```

> **NOTE**
>
> This approach ensures that the code establishes a connection before the event handler executes.

The code starts the connection and then passes it a function to handle the click event on the **Send** button in the HTML page.

Get the code

- SignalR Wiki

Next steps

In this tutorial you:

- Set up the project
- Ran the sample
- Examined the code

Advance to the next article to learn how to use SignalR and MVC 5.

SignalR 2 and MVC 5

Tutorial: Real-time chat with SignalR 2 and MVC 5

2/20/2020 • 6 minutes to read • Edit Online

This tutorial shows how to use ASP.NET SignalR 2 to create a real-time chat application. You add SignalR to an MVC 5 application and create a chat view to send and display messages.

In this tutorial, you:

- Set up the project
- Run the sample
- Examine the code

> **WARNING**
>
> This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

Prerequisites

- Visual Studio 2017 with the **ASP.NET and web development** workload.

Set up the Project

This section shows how to use Visual Studio 2017 and SignalR 2 to create an empty ASP.NET MVC 5 application, add the SignalR library, and create the chat application.

1. In Visual Studio, create a C# ASP.NET application that targets .NET Framework 4.5, name it SignalRChat, and click OK.

2. In **New ASP.NET Web Application - SignalRMvcChat**, select **MVC** and then select **Change**

Authentication.

3. In **Change Authentication**, select **No Authentication** and click **OK**.

4. In **New ASP.NET Web Application - SignalRMvcChat**, select **OK**.
5. In **Solution Explorer**, right-click the project and select **Add** > **New Item**.
6. In **Add New Item - SignalRChat**, select **Installed** > **Visual C#** > **Web** > **SignalR** and then select **SignalR Hub Class (v2)**.
7. Name the class *ChatHub* and add it to the project.

   This step creates the *ChatHub.cs* class file and adds a set of script files and assembly references that support SignalR to the project.

8. Replace the code in the new *ChatHub.cs* class file with this code:

```
using System;
using System.Web;
using Microsoft.AspNet.SignalR;
namespace SignalRChat
{
    public class ChatHub : Hub
    {
        public void Send(string name, string message)
        {
            // Call the addNewMessageToPage method to update clients.
            Clients.All.addNewMessageToPage(name, message);
        }
    }
}
```

9. In **Solution Explorer**, right-click the project and select **Add** > **Class**.
10. Name the new class *Startup* and add it to the project.
11. Replace the code in the *Startup.cs* class file with this code:

```
using Owin;
using Microsoft.Owin;
[assembly: OwinStartup(typeof(SignalRChat.Startup))]
namespace SignalRChat
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            // Any connection or hub wire up and configuration should go here
            app.MapSignalR();
        }
    }
}
```

12. In **Solution Explorer**, select **Controllers** > **HomeController.cs**.

13. Add this method to the *HomeController.cs*.

```
public ActionResult Chat()
{
    return View();
}
```

    This method returns the **Chat** view that you create in a later step.

14. In **Solution Explorer**, right-click **Views** > **Home**, and select **Add** > **View**.

15. In **Add View**, name the new view **Chat** and select **Add**.

16. Replace the contents of **Chat.cshtml** with this code:

```
@{
    ViewBag.Title = "Chat";
}
<h2>Chat</h2>
<div class="container">
    <input type="text" id="message" />
    <input type="button" id="sendmessage" value="Send" />
    <input type="hidden" id="displayname" />
    <ul id="discussion">
    </ul>
</div>
@section scripts {
    <!--Script references. -->
    <!--The jQuery library is required and is referenced by default in _Layout.cshtml. -->
    <!--Reference the SignalR library. -->
    <script src="~/Scripts/jquery.signalR-2.1.0.min.js"></script>
    <!--Reference the autogenerated SignalR hub script. -->
    <script src="~/signalr/hubs"></script>
    <!--SignalR script to update the chat page and send messages.-->
    <script>
        $(function () {
            // Reference the auto-generated proxy for the hub.
            var chat = $.connection.chatHub;
            // Create a function that the hub can call back to display messages.
            chat.client.addNewMessageToPage = function (name, message) {
                // Add the message to the page.
                $('#discussion').append('<li><strong>' + htmlEncode(name)
                    + '</strong>: ' + htmlEncode(message) + '</li>');
            };
            // Get the user name and store it to prepend to messages.
            $('#displayname').val(prompt('Enter your name:', ''));
            // Set initial focus to message input box.
            $('#message').focus();
            // Start the connection.
            $.connection.hub.start().done(function () {
                $('#sendmessage').click(function () {
                    // Call the Send method on the hub.
                    chat.server.send($('#displayname').val(), $('#message').val());
                    // Clear text box and reset focus for next comment.
                    $('#message').val('').focus();
                });
            });
        });
        // This optional function html-encodes messages for display in the page.
        function htmlEncode(value) {
            var encodedValue = $('<div />').text(value).html();
            return encodedValue;
        }
    </script>
}
```

17. In **Solution Explorer**, expand **Scripts**.

    Script libraries for jQuery and SignalR are visible in the project.

> **IMPORTANT**
>
> The package manager may have installed a later version of the SignalR scripts.

18. Check that the script references in the code block correspond to the versions of the script files in the project.

    Script references from the original code block:

```
<!--Script references. -->
<!--The jQuery library is required and is referenced by default in _Layout.cshtml. -->
<!--Reference the SignalR library. -->
<script src="~/Scripts/jquery.signalR-2.1.0.min.js"></script>
```

19. If they don't match, update the *.cshtml* file.

20. From the menu bar, select **File** > **Save All**.

Run the Sample

1. In the toolbar, turn on **Script Debugging** and then select the play button to run the sample in Debug mode.

2. When the browser opens, enter a name for your chat identity.

3. Copy the URL from the browser, open two other browsers, and paste the URLs into the address bars.

4. In each browser, enter a unique name.

5. Now, add a comment and select **Send**. Repeat that in the other browsers. The comments appear in real time.

> **NOTE**
>
> This simple chat application does not maintain the discussion context on the server. The hub broadcasts comments to all current users. Users who join the chat later will see messages added from the time they join.

See how the chat application runs in three different browsers. When Tom, Anand, and Susan send messages, all browsers update in real time:

6. In **Solution Explorer**, inspect the **Script Documents** node for the running application. There's a script file named *hubs* that the SignalR library generates at runtime. This file manages the communication between jQuery script and server-side code.

Examine the Code

The SignalR chat application demonstrates two basic SignalR development tasks. It shows you how to create a hub. The server uses that hub as the main coordination object. The hub uses the SignalR jQuery library to send and receive messages.

SignalR Hubs in the ChatHub.cs

In the code sample, the `ChatHub` class derives from the `Microsoft.AspNet.SignalR.Hub` class. Deriving from the `Hub` class is a useful way to build a SignalR application. You can create public methods on your hub class and then access those methods by calling them from scripts in a web page.

In the chat code, clients call the `ChatHub.Send` method to send a new message. The hub in turn sends the message to all clients by calling `Clients.All.addNewMessageToPage`.

The `Send` method demonstrates several hub concepts:

- Declare public methods on a hub so that clients can call them.
- Use the `Microsoft.AspNet.SignalR.Hub.Clients` dynamic property to communicate with all clients connected to this hub.
- Call a function on the client (like the `addNewMessageToPage` function) to update clients.

```
public class ChatHub : Hub
{
    public void Send(string name, string message)
    {
        Clients.All.addNewMessageToPage(name, message);
    }
}
```

SignalR and jQuery Chat.cshtml

The *Chat.cshtml* view file in the code sample shows how to use the SignalR jQuery library to communicate with a SignalR hub. The code carries out many important tasks. It creates a reference to the autogenerated proxy for the hub, declares a function that the server can call to push content to clients, and it starts a connection to send messages to the hub.

```
var chat = $.connection.chatHub;
```

> **NOTE**
>
> In JavaScript, the reference to the server class and its members is in camelCase. The code sample references the C# `ChatHub` class in JavaScript as `chatHub`.

In this code block, you create a callback function in the script.

```
chat.client.addNewMessageToPage = function (name, message) {
    // Add the message to the page.
    $('#discussion').append('<li><strong>' + htmlEncode(name)
        + '</strong>: ' + htmlEncode(message) + '</li>');
};
```

The hub class on the server calls this function to push content updates to each client. The optional call to the `htmlEncode` function shows a way to HTML encode the message content before displaying it in the page. It's a way to prevent script injection.

This code opens a connection with the hub.

```
$.connection.hub.start().done(function () {
    $('#sendmessage').click(function () {
        // Call the Send method on the hub.
        chat.server.send($('#displayname').val(), $('#message').val());
        // Clear text box and reset focus for next comment.
        $('#message').val('').focus();
    });
});
```

> **NOTE**
>
> This approach ensures that you establish a connection before the event handler executes.

The code starts the connection and then passes it a function to handle the click event on the **Send** button in the Chat page.

Get the code

Next steps

In this tutorial, you:

- Set up the project
- Ran the sample
- Examined the code

Advance to the next article to learn how to create a web application that uses ASP.NET SignalR 2 to provide high-frequency messaging functionality.

Web app with high-frequency messaging

Tutorial: Create high-frequency real-time app with SignalR 2

2/20/2020 • 12 minutes to read • Edit Online

This tutorial shows how to create a web application that uses ASP.NET SignalR 2 to provide high-frequency messaging functionality. In this case, "high-frequency messaging" means the server sends updates at a fixed rate. You send up to 10 messages a second.

The application you create displays a shape that users can drag. The server updates the position of the shape in all connected browsers to match the position of the dragged shape using timed updates.

Concepts introduced in this tutorial have applications in real-time gaming and other simulation applications.

In this tutorial, you:

- Set up the project
- Create the base application
- Map to the hub when app starts
- Add the client
- Run the app
- Add the client loop
- Add the server loop
- Add smooth animation

> **WARNING**
>
> This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

Prerequisites

- Visual Studio 2017 with the **ASP.NET and web development** workload.

Set up the project

In this section, you create the project in Visual Studio 2017.

This section shows how to use Visual Studio 2017 to create an empty ASP.NET Web Application and add the SignalR and jQuery.UI libraries.

1. In Visual Studio, create an ASP.NET Web Application.

2. In the **New ASP.NET Web Application - MoveShapeDemo** window, leave **Empty** selected and select **OK**.

3. In **Solution Explorer**, right-click the project and select **Add** > **New Item**.

4. In **Add New Item - MoveShapeDemo**, select **Installed** > **Visual C#** > **Web** > **SignalR** and then select **SignalR Hub Class (v2)**.

5. Name the class *MoveShapeHub* and add it to the project.

   This step creates the *MoveShapeHub.cs* class file. Simultaneously, it adds a set of script files and assembly references that support SignalR to the project.

6. Select **Tools** > **NuGet Package Manager** > **Package Manager Console**.

7. In **Package Manager Console**, run this command:

   ```
   Install-Package jQuery.UI.Combined
   ```

   The command installs the jQuery UI library. You use it to animate the shape.

8. In **Solution Explorer**, expand the Scripts node.

Script libraries for jQuery, jQueryUI, and SignalR are visible in the project.

Create the base application

In this section, you create a browser application. The app sends the location of the shape to the server during each mouse move event. The server broadcasts this information to all other connected clients in real time. You learn more about this application in later sections.

1. Open the *MoveShapeHub.cs* file.

2. Replace the code in the *MoveShapeHub.cs* file with this code:

```
using Microsoft.AspNet.SignalR;
using Newtonsoft.Json;

namespace MoveShapeDemo
{
    public class MoveShapeHub : Hub
    {
        public void UpdateModel(ShapeModel clientModel)
        {
            clientModel.LastUpdatedBy = Context.ConnectionId;
            // Update the shape model within our broadcaster
            Clients.AllExcept(clientModel.LastUpdatedBy).updateShape(clientModel);
        }
    }
    public class ShapeModel
    {
        // We declare Left and Top as lowercase with
        // JsonProperty to sync the client and server models
        [JsonProperty("left")]
        public double Left { get; set; }
        [JsonProperty("top")]
        public double Top { get; set; }
        // We don't want the client to get the "LastUpdatedBy" property
        [JsonIgnore]
        public string LastUpdatedBy { get; set; }
    }
}
```

3. Save the file.

The `MoveShapeHub` class is an implementation of a SignalR hub. As in the Getting Started with SignalR tutorial, the hub has a method that the clients call directly. In this case, the client sends an object with the new X and Y coordinates of the shape to the server. Those coordinates get broadcasted to all other connected clients. SignalR automatically serializes this object using JSON.

The app sends the `ShapeModel` object to the client. It has members to store the position of the shape. The version of the object on the server also has a member to track which client's data is being stored. This object prevents the server from sending a client's data back to itself. This member uses the `JsonIgnore` attribute to keep the application from serializing the data and sending it back to the client.

Map to the hub when app starts

Next, you set up mapping to the hub when the application starts. In SignalR 2, adding an OWIN startup class creates the mapping.

1. In **Solution Explorer**, right-click the project and select **Add** > **New Item**.
2. In **Add New Item - MoveShapeDemo** select **Installed** > **Visual C#** > **Web** and then select **OWIN Startup Class**.
3. Name the class *Startup* and select **OK**.
4. Replace the default code in the *Startup.cs* file with this code:

```
using Microsoft.Owin;
using Owin;

[assembly: OwinStartup(typeof(MoveShapeDemo.Startup))]
namespace MoveShapeDemo
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            // Any connection or hub wire up and configuration should go here
            app.MapSignalR();
        }
    }
}
```

The OWIN startup class calls `MapSignalR` when the app executes the `Configuration` method. The app adds the class to OWIN's startup process using the `OwinStartup` assembly attribute.

Add the client

Add the HTML page for the client.

1. In **Solution Explorer**, right-click the project and select **Add** > **HTML Page**.
2. Name the page **Default** and select **OK**.
3. In **Solution Explorer**, right-click *Default.html* and select **Set as Start Page**.
4. Replace the default code in the *Default.html* file with this code:

```
<!DOCTYPE html>
<html>
<head>
    <title>SignalR MoveShape Demo</title>
    <style>
        #shape {
            width: 100px;
            height: 100px;
            background-color: #FF0000;
        }
    </style>
</head>
<body>
<script src="Scripts/jquery-1.10.2.min.js"></script>
<script src="Scripts/jquery-ui-1.10.4.min.js"></script>
<script src="Scripts/jquery.signalR-2.1.0.js"></script>
<script src="/signalr/hubs"></script>
<script>
 $(function () {
            var moveShapeHub = $.connection.moveShapeHub,
            $shape = $("#shape"),
            shapeModel = {
                left: 0,
                top: 0
            };
            moveShapeHub.client.updateShape = function (model) {
                shapeModel = model;
                $shape.css({ left: model.left, top: model.top });
            };
            $.connection.hub.start().done(function () {
                $shape.draggable({
                    drag: function () {
                        shapeModel = $shape.offset();
                        moveShapeHub.server.updateModel(shapeModel);
                    }
                });
            });
        });
</script

    <div id="shape" />
</body>
</html>
```

5. In **Solution Explorer**, expand **Scripts**.

   Script libraries for jQuery and SignalR are visible in the project.

   > **IMPORTANT**
   >
   > The package manager installs a later version of the SignalR scripts.

6. Update the script references in the code block to correspond to the versions of the script files in the project.

This HTML and JavaScript code creates a red `div` called `shape`. It enables the shape's dragging behavior using the jQuery library and uses the `drag` event to send the shape's position to the server.

Run the app

You can run the app to se`e it work. When you drag the shape around a browser window, the shape moves in the other browsers too.

1. In the toolbar, turn on **Script Debugging** and then select the play button to run the application in Debug mode.

   A browser window opens with the red shape in the upper-right corner.

2. Copy the page's URL.

3. Open another browser and paste the URL into the address bar.

4. Drag the shape in one of the browser windows. The shape in the other browser window follows.

While the application functions using this method, it's not a recommended programming model. There's no upper limit to the number of messages getting sent. As a result, the clients and server get overwhelmed with messages and performance degrades. Also, the app displays a disjointed animation on the client. This jerky animation happens because the shape moves instantly by each method. It's better if the shape moves smoothly to each new location. Next, you learn how to fix those issues.

Add the client loop

Sending the location of the shape on every mouse move event creates an unnecessary amount of network traffic. The app needs to throttle the messages from the client.

Use the javascript `setInterval` function to set up a loop that sends new position information to the server at a fixed rate. This loop is a basic representation of a "game loop." It's a repeatedly called function that drives all the functionality of a game.

1. Replace the client code in the *Default.html* file with this code:

```
<!DOCTYPE html>
<html>
<head>
<title>SignalR MoveShape Demo</title>
<style>
    #shape {
        width: 100px;
        height: 100px;
        background-color: #FF0000;
    }
</style>
</head>
<body>
<script src="Scripts/jquery-1.10.2.min.js"></script>
<script src="Scripts/jquery-ui-1.10.4.min.js"></script>
<script src="Scripts/jquery.signalR-2.1.0.js"></script>
<script src="/signalr/hubs"></script>
<script>
    $(function () {
        var moveShapeHub = $.connection.moveShapeHub,
            $shape = $("#shape"),
            // Send a maximum of 10 messages per second
            // (mouse movements trigger a lot of messages)
            messageFrequency = 10,
            // Determine how often to send messages in
            // time to abide by the messageFrequency
            updateRate = 1000 / messageFrequency,
            shapeModel = {
                left: 0,
                top: 0
            },
            moved = false;
        moveShapeHub.client.updateShape = function (model) {
            shapeModel = model;
            $shape.css({ left: model.left, top: model.top });
        };
        $.connection.hub.start().done(function () {
            $shape.draggable({
                drag: function () {
                    shapeModel = $shape.offset();
                    moved = true;
                }
            });
            // Start the client side server update interval
            setInterval(updateServerModel, updateRate);
        });
        function updateServerModel() {
            // Only update server if we have a new movement
            if (moved) {
                moveShapeHub.server.updateModel(shapeModel);
                moved = false;
            }
        }
    });
</script>

<div id="shape" />
</body>
</html>
```

IMPORTANT

You have to replace the script references again. They must match the versions of the scripts in the project.

This new code adds the `updateServerModel` function. It gets called on a fixed frequency. The function sends the position data to the server whenever the `moved` flag indicates that there's new position data to send.

2. Select the play button to start the application
3. Copy the page's URL.
4. Open another browser and paste the URL into the address bar.
5. Drag the shape in one of the browser windows. The shape in the other browser window follows.

Since the app throttles the number of messages that get sent to the server, the animation won't appear as smooth did at first.

Add the server loop

In the current application, messages sent from the server to the client go out as often as they're received. This network traffic presents a similar problem as we see on the client.

The app can send messages more often than they're needed. The connection can become flooded as a result. This section describes how to update the server to add a timer that throttles the rate of the outgoing messages.

1. Replace the contents of `MoveShapeHub.cs` with this code:

```
using System;
using System.Threading;
using Microsoft.AspNet.SignalR;
using Newtonsoft.Json;

namespace MoveShapeDemo
{
    public class Broadcaster
    {
        private readonly static Lazy<Broadcaster> _instance =
            new Lazy<Broadcaster>(() => new Broadcaster());
        // We're going to broadcast to all clients a maximum of 25 times per second
        private readonly TimeSpan BroadcastInterval =
            TimeSpan.FromMilliseconds(40);
        private readonly IHubContext _hubContext;
        private Timer _broadcastLoop;
        private ShapeModel _model;
        private bool _modelUpdated;
        public Broadcaster()
        {
            // Save our hub context so we can easily use it
            // to send to its connected clients
            _hubContext = GlobalHost.ConnectionManager.GetHubContext<MoveShapeHub>();
            _model = new ShapeModel();
            _modelUpdated = false;
            // Start the broadcast loop
            _broadcastLoop = new Timer(
                BroadcastShape,
                null,
                BroadcastInterval,
                BroadcastInterval);
        }
        public void BroadcastShape(object state)
        {
            // No need to send anything if our model hasn't changed
            if (_modelUpdated)
            {
                // This is how we can access the Clients property
                // in a static hub method or outside of the hub entirely
                _hubContext.Clients.AllExcept(_model.LastUpdatedBy).updateShape(_model);
                _modelUpdated = false;
```

```
            }
        }
        public void UpdateShape(ShapeModel clientModel)
        {
            _model = clientModel;
            _modelUpdated = true;
        }
        public static Broadcaster Instance
        {
            get
            {
                return _instance.Value;
            }
        }
    }

    public class MoveShapeHub : Hub
    {
        // Is set via the constructor on each creation
        private Broadcaster _broadcaster;
        public MoveShapeHub()
            : this(Broadcaster.Instance)
        {
        }
        public MoveShapeHub(Broadcaster broadcaster)
        {
            _broadcaster = broadcaster;
        }
        public void UpdateModel(ShapeModel clientModel)
        {
            clientModel.LastUpdatedBy = Context.ConnectionId;
            // Update the shape model within our broadcaster
            _broadcaster.UpdateShape(clientModel);
        }
    }
    public class ShapeModel
    {
        // We declare Left and Top as lowercase with
        // JsonProperty to sync the client and server models
        [JsonProperty("left")]
        public double Left { get; set; }
        [JsonProperty("top")]
        public double Top { get; set; }
        // We don't want the client to get the "LastUpdatedBy" property
        [JsonIgnore]
        public string LastUpdatedBy { get; set; }
    }

}
```

2. Select the play button to start the application.
3. Copy the page's URL.
4. Open another browser and paste the URL into the address bar.
5. Drag the shape in one of the browser windows.

This code expands the client to add the `Broadcaster` class. The new class throttles the outgoing messages using the `Timer` class from the .NET framework.

It's good to learn that the hub itself is transitory. It's created every time it's needed. So the app creates the `Broadcaster` as a singleton. It uses lazy initialization to defer the `Broadcaster`'s creation until it's needed. That guarantees that the app creates the first hub instance completely before starting the timer.

The call to the clients' `UpdateShape` function is then moved out of the hub's `UpdateModel` method. It's no longer

called immediately whenever the app receives incoming messages. Instead, the app sends the messages to the clients at a rate of 25 calls per second. The process is managed by the `_broadcastLoop` timer from within the `Broadcaster` class.

Lastly, instead of calling the client method from the hub directly, the `Broadcaster` class needs to get a reference to the currently operating `_hubContext` hub. It gets the reference with the `GlobalHost`.

Add smooth animation

The application is almost finished, but we could make one more improvement. The app moves the shape on the client in response to server messages. Instead of setting the position of the shape to the new location given by the server, use the JQuery UI library's `animate` function. It can move the shape smoothly between its current and new position.

1. Update the client's `updateShape` method in the *Default.html* file to look like the highlighted code:

```
<!DOCTYPE html>
<html>
<head>
    <title>SignalR MoveShape Demo</title>
    <style>
        #shape {
            width: 100px;
            height: 100px;
            background-color: #FF0000;
        }
    </style>
</head>
<body>
<script src="Scripts/jquery-1.10.2.min.js"></script>
<script src="Scripts/jquery-ui-1.10.4.min.js"></script>
<script src="Scripts/jquery.signalR-2.1.0.js"></script>
<script src="/signalr/hubs"></script>
<script>
        $(function () {
            var moveShapeHub = $.connection.moveShapeHub,
                $shape = $("#shape"),
                // Send a maximum of 10 messages per second
                // (mouse movements trigger a lot of messages)
                messageFrequency = 10,
                // Determine how often to send messages in
                // time to abide by the messageFrequency
                updateRate = 1000 / messageFrequency,
                shapeModel = {
                    left: 0,
                    top: 0
                },
                moved = false;
            moveShapeHub.client.updateShape = function (model) {
                 shapeModel = model;
                 // Gradually move the shape towards the new location (interpolate)
                 // The updateRate is used as the duration because by the time
                 // we get to the next location we want to be at the "last" location
                 // We also clear the animation queue so that we start a new
                 // animation and don't lag behind.
                 $shape.animate(shapeModel, { duration: updateRate, queue: false });
            };
            $.connection.hub.start().done(function () {
                $shape.draggable({
                    drag: function () {
                        shapeModel = $shape.offset();
                        moved = true;
                    }
                });
                // Start the client side server update interval
                setInterval(updateServerModel, updateRate);
            });
            function updateServerModel() {
                // Only update server if we have a new movement
                if (moved) {
                    moveShapeHub.server.updateModel(shapeModel);
                    moved = false;
                }
            }
        });
</script>

    <div id="shape" />
</body>
</html>
```

2. Select the play button to start the application.

3. Copy the page's URL.
4. Open another browser and paste the URL into the address bar.
5. Drag the shape in one of the browser windows.

The movement of the shape in the other window appears less jerky. The app interpolates its movement over time rather than being set once per incoming message.

This code moves the shape from the old location to the new one. The server gives the position of the shape over the course of the animation interval. In this case, that's 100 milliseconds. The app clears any previous animation running on the shape before the new animation starts.

Additional resources

The communication paradigm you just learned about is useful for developing online games and other simulations, like the ShootR game created with SignalR.

For more about SignalR, see the following resources:

- SignalR Project
- SignalR GitHub and Samples
- SignalR Wiki

Next steps

In this tutorial, you:

- Set up the project
- Created the base application
- Mapped to the hub when app starts
- Added the client
- Ran the app
- Added the client loop
- Added the server loop
- Added smooth animation

Advance to the next article to learn how to create a web application that uses ASP.NET SignalR 2 to provide server broadcast functionality.

SignalR 2 and server broadcasting

Tutorial: Server broadcast with SignalR 2

2/20/2020 • 26 minutes to read • Edit Online

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This tutorial shows how to create a web application that uses ASP.NET SignalR 2 to provide server broadcast functionality. Server broadcast means that the server starts the communications sent to clients.

The application that you'll create in this tutorial simulates a stock ticker, a typical scenario for server broadcast functionality. Periodically, the server randomly updates stock prices and broadcast the updates to all connected clients. In the browser, the numbers and symbols in the **Change** and **%** columns dynamically change in response to notifications from the server. If you open additional browsers to the same URL, they all show the same data and the same changes to the data simultaneously.

In this tutorial, you:

- Create the project
- Set up the server code
- Examine the server code
- Set up the client code
- Examine the client code
- Test the application
- Enable logging

> **IMPORTANT**
>
> If you don't want to work through the steps of building the application, you can install the SignalR.Sample package in a new Empty ASP.NET Web Application project. If you install the NuGet package without performing the steps in this tutorial, you must follow the instructions in the *readme.txt* file. To run the package you need to add an OWIN startup class which calls the `ConfigureSignalR` method in the installed package. You will receive an error if you do not add the OWIN startup class. See the Install the StockTicker sample section of this article.

Prerequisites

- Visual Studio 2017 with the **ASP.NET and web development** workload.

Create the project

This section shows how to use Visual Studio 2017 to create an empty ASP.NET Web Application.

1. In Visual Studio, create an ASP.NET Web Application.

2. In the **New ASP.NET Web Application - SignalR.StockTicker** window, leave **Empty** selected and select **OK**.

Set up the server code

In this section, you set up the code that runs on the server.

Create the Stock class

You begin by creating the *Stock* model class that you'll use to store and transmit information about a stock.

1. In **Solution Explorer**, right-click the project and select **Add** > **Class**.

2. Name the class *Stock* and add it to the project.

3. Replace the code in the *Stock.cs* file with this code:

```
using System;

namespace SignalR.StockTicker
{
    public class Stock
    {
        private decimal _price;

        public string Symbol { get; set; }

        public decimal Price
        {
            get
            {
                return _price;
            }
            set
            {
                if (_price == value)
                {
                    return;
                }

                _price = value;

                if (DayOpen == 0)
                {
                    DayOpen = _price;
                }
            }
        }

        public decimal DayOpen { get; private set; }

        public decimal Change
        {
            get
            {
                return Price - DayOpen;
            }
        }

        public double PercentChange
        {
            get
            {
                return (double)Math.Round(Change / Price, 4);
            }
        }
    }
}
```

The two properties that you'll set when you create stocks are `Symbol` (for example, MSFT for Microsoft) and `Price`. The other properties depend on how and when you set `Price`. The first time you set `Price`, the value gets propagated to `DayOpen`. After that, when you set `Price`, the app calculates the `Change` and `PercentChange` property values based on the difference between `Price` and `DayOpen`.

Create the StockTickerHub and StockTicker classes

You'll use the SignalR Hub API to handle server-to-client interaction. A `StockTickerHub` class that derives from the SignalR `Hub` class will handle receiving connections and method calls from clients. You also need to maintain stock data and run a `Timer` object. The `Timer` object will periodically trigger price updates independent of client connections. You can't put these functions in a `Hub` class, because Hubs are transient. The app creates a `Hub` class instance for each task on the hub, like connections and calls from the client to the server. So the mechanism

that keeps stock data, updates prices, and broadcasts the price updates has to run in a separate class. You'll name the class `StockTicker`.

You only want one instance of the `StockTicker` class to run on the server, so you'll need to set up a reference from each `StockTickerHub` instance to the singleton `StockTicker` instance. The `StockTicker` class has to broadcast to clients because it has the stock data and triggers updates, but `StockTicker` isn't a `Hub` class. The `StockTicker` class has to get a reference to the SignalR Hub connection context object. It can then use the SignalR connection context object to broadcast to clients.

Create StockTickerHub.cs

1. In **Solution Explorer**, right-click the project and select **Add** > **New Item**.
2. In **Add New Item - SignalR.StockTicker**, select **Installed** > **Visual C#** > **Web** > **SignalR** and then select **SignalR Hub Class (v2)**.
3. Name the class *StockTickerHub* and add it to the project.

   This step creates the *StockTickerHub.cs* class file. Simultaneously, it adds a set of script files and assembly references that supports SignalR to the project.
4. Replace the code in the *StockTickerHub.cs* file with this code:

```
using System.Collections.Generic;
using Microsoft.AspNet.SignalR;
using Microsoft.AspNet.SignalR.Hubs;

namespace SignalR.StockTicker
{
    [HubName("stockTickerMini")]
    public class StockTickerHub : Hub
    {
        private readonly StockTicker _stockTicker;

        public StockTickerHub() : this(StockTicker.Instance) { }

        public StockTickerHub(StockTicker stockTicker)
        {
            _stockTicker = stockTicker;
        }

        public IEnumerable<Stock> GetAllStocks()
        {
            return _stockTicker.GetAllStocks();
        }
    }
}
```

5. Save the file.

The app uses the Hub class to define methods the clients can call on the server. You're defining one method: `GetAllStocks()`. When a client initially connects to the server, it will call this method to get a list of all of the stocks with their current prices. The method can run synchronously and return `IEnumerable<Stock>` because it's returning data from memory.

If the method had to get the data by doing something that would involve waiting, like a database lookup or a web service call, you would specify `Task<IEnumerable<Stock>>` as the return value to enable asynchronous processing. For more information, see ASP.NET SignalR Hubs API Guide - Server - When to execute asynchronously.

The `HubName` attribute specifies how the app will reference the Hub in JavaScript code on the client. The default name on the client if you don't use this attribute, is a camelCase version of the class name, which in this case would be `stockTickerHub`.

As you'll see later when you create the `StockTicker` class, the app creates a singleton instance of that class in its static `Instance` property. That singleton instance of `StockTicker` is in memory no matter how many clients connect or disconnect. That instance is what the `GetAllStocks()` method uses to return current stock information.

Create StockTicker.cs

1. In **Solution Explorer**, right-click the project and select **Add** > **Class**.

2. Name the class *StockTicker* and add it to the project.

3. Replace the code in the *StockTicker.cs* file with this code:

```
using System;
using System.Collections.Concurrent;
using System.Collections.Generic;
using System.Threading;
using Microsoft.AspNet.SignalR;
using Microsoft.AspNet.SignalR.Hubs;

namespace SignalR.StockTicker
{
    public class StockTicker
    {
```

```
        // Singleton instance
        private readonly static Lazy<StockTicker> _instance = new Lazy<StockTicker>(() => new
StockTicker(GlobalHost.ConnectionManager.GetHubContext<StockTickerHub>().Clients));

        private readonly ConcurrentDictionary<string, Stock> _stocks = new
ConcurrentDictionary<string, Stock>();

        private readonly object _updateStockPricesLock = new object();

        //stock can go up or down by a percentage of this factor on each change
        private readonly double _rangePercent = .002;

        private readonly TimeSpan _updateInterval = TimeSpan.FromMilliseconds(250);
        private readonly Random _updateOrNotRandom = new Random();

        private readonly Timer _timer;
        private volatile bool _updatingStockPrices = false;

        private StockTicker(IHubConnectionContext<dynamic> clients)
        {
            Clients = clients;

            _stocks.Clear();
            var stocks = new List<Stock>
            {
                new Stock { Symbol = "MSFT", Price = 30.31m },
                new Stock { Symbol = "APPL", Price = 578.18m },
                new Stock { Symbol = "GOOG", Price = 570.30m }
            };
            stocks.ForEach(stock => _stocks.TryAdd(stock.Symbol, stock));

            _timer = new Timer(UpdateStockPrices, null, _updateInterval, _updateInterval);

        }

        public static StockTicker Instance
        {
            get
            {
                return _instance.Value;
            }
        }

        private IHubConnectionContext<dynamic> Clients
        {
            get;
            set;
        }

        public IEnumerable<Stock> GetAllStocks()
        {
            return _stocks.Values;
        }

        private void UpdateStockPrices(object state)
        {
            lock (_updateStockPricesLock)
            {
                if (!_updatingStockPrices)
                {
                    _updatingStockPrices = true;

                    foreach (var stock in _stocks.Values)
                    {
                        if (TryUpdateStockPrice(stock))
                        {
                            BroadcastStockPrice(stock);
                        }
                    }
```

```
                _updatingStockPrices = false;
            }
        }
    }

    private bool TryUpdateStockPrice(Stock stock)
    {
        // Randomly choose whether to update this stock or not
        var r = _updateOrNotRandom.NextDouble();
        if (r > .1)
        {
            return false;
        }

        // Update the stock price by a random factor of the range percent
        var random = new Random((int)Math.Floor(stock.Price));
        var percentChange = random.NextDouble() * _rangePercent;
        var pos = random.NextDouble() > .51;
        var change = Math.Round(stock.Price * (decimal)percentChange, 2);
        change = pos ? change : -change;

        stock.Price += change;
        return true;
    }

    private void BroadcastStockPrice(Stock stock)
    {
        Clients.All.updateStockPrice(stock);
    }

  }
}
```

Since all threads will be running the same instance of StockTicker code, the StockTicker class has to be thread-safe.

Examine the server code

If you examine the server code, it will help you understand how the app works.

Storing the singleton instance in a static field

The code initializes the static `_instance` field that backs the `Instance` property with an instance of the class. Because the constructor is private, it's the only instance of the class that the app can create. The app uses Lazy initialization for the `_instance` field. It's not for performance reasons. It's to make sure the instance creation is thread-safe.

```
private readonly static Lazy<StockTicker> _instance = new Lazy<StockTicker>(() => new
StockTicker(GlobalHost.ConnectionManager.GetHubContext<StockTickerHub>().Clients));

public static StockTicker Instance
{
    get
    {
        return _instance.Value;
    }
}
```

Each time a client connects to the server, a new instance of the StockTickerHub class running in a separate thread gets the StockTicker singleton instance from the `StockTicker.Instance` static property, as you saw earlier in the `StockTickerHub` class.

Storing stock data in a ConcurrentDictionary

The constructor initializes the `_stocks` collection with some sample stock data, and `GetAllStocks` returns the stocks. As you saw earlier, this collection of stocks is returned by `StockTickerHub.GetAllStocks`, which is a server method in the `Hub` class that clients can call.

```
private readonly ConcurrentDictionary<string, Stock> _stocks = new ConcurrentDictionary<string, Stock>();
```

```
private StockTicker(IHubConnectionContext<dynamic> clients)
{
    Clients = clients;

    _stocks.Clear();
    var stocks = new List<Stock>
    {
        new Stock { Symbol = "MSFT", Price = 30.31m },
        new Stock { Symbol = "APPL", Price = 578.18m },
        new Stock { Symbol = "GOOG", Price = 570.30m }
    };
    stocks.ForEach(stock => _stocks.TryAdd(stock.Symbol, stock));

    _timer = new Timer(UpdateStockPrices, null, _updateInterval, _updateInterval);
}

public IEnumerable<Stock> GetAllStocks()
{
    return _stocks.Values;
}
```

The stocks collection is defined as a ConcurrentDictionary type for thread safety. As an alternative, you could use a Dictionary object and explicitly lock the dictionary when you make changes to it.

For this sample application, it's OK to store application data in memory and to lose the data when the app disposes of the `StockTicker` instance. In a real application, you would work with a back-end data store like a database.

Periodically updating stock prices

The constructor starts up a `Timer` object that periodically calls methods that update stock prices on a random basis.

```
_timer = new Timer(UpdateStockPrices, null, _updateInterval, _updateInterval);

private void UpdateStockPrices(object state)
{
    lock (_updateStockPricesLock)
    {
        if (!_updatingStockPrices)
        {
            _updatingStockPrices = true;

            foreach (var stock in _stocks.Values)
            {
                if (TryUpdateStockPrice(stock))
                {
                    BroadcastStockPrice(stock);
                }
            }

            _updatingStockPrices = false;
        }
    }
}

private bool TryUpdateStockPrice(Stock stock)
{
    // Randomly choose whether to update this stock or not
    var r = _updateOrNotRandom.NextDouble();
    if (r > .1)
    {
        return false;
    }

    // Update the stock price by a random factor of the range percent
    var random = new Random((int)Math.Floor(stock.Price));
    var percentChange = random.NextDouble() * _rangePercent;
    var pos = random.NextDouble() > .51;
    var change = Math.Round(stock.Price * (decimal)percentChange, 2);
    change = pos ? change : -change;

    stock.Price += change;
    return true;
}
```

`Timer` calls `UpdateStockPrices`, which passes in null in the state parameter. Before updating prices, the app takes a lock on the `_updateStockPricesLock` object. The code checks if another thread is already updating prices, and then it calls `TryUpdateStockPrice` on each stock in the list. The `TryUpdateStockPrice` method decides whether to change the stock price, and how much to change it. If the stock price changes, the app calls `BroadcastStockPrice` to broadcast the stock price change to all connected clients.

The `_updatingStockPrices` flag designated volatile to make sure it is thread-safe.

```
private volatile bool _updatingStockPrices = false;
```

In a real application, the `TryUpdateStockPrice` method would call a web service to look up the price. In this code, the app uses a random number generator to make changes randomly.

Getting the SignalR context so that the StockTicker class can broadcast to clients

Because the price changes originate here in the `StockTicker` object, it's the object that needs to call an `updateStockPrice` method on all connected clients. In a `Hub` class, you have an API for calling client methods, but `StockTicker` doesn't derive from the `Hub` class and doesn't have a reference to any `Hub` object. To broadcast to connected clients, the `StockTicker` class has to get the SignalR context instance for the `StockTickerHub` class and

use that to call methods on clients.

The code gets a reference to the SignalR context when it creates the singleton class instance, passes that reference to the constructor, and the constructor puts it in the `Clients` property.

There are two reasons why you want to get the context only once: getting the context is an expensive task, and getting it once makes sure the app preserves the intended order of messages sent to the clients.

```
private readonly static Lazy<StockTicker> _instance =
    new Lazy<StockTicker>(() => new StockTicker(GlobalHost.ConnectionManager.GetHubContext<StockTickerHub>
().Clients));

private StockTicker(IHubConnectionContext<dynamic> clients)
{
    Clients = clients;

    // Remainder of constructor ...
}

private IHubConnectionContext<dynamic> Clients
{
    get;
    set;
}

private void BroadcastStockPrice(Stock stock)
{
    Clients.All.updateStockPrice(stock);
}
```

Getting the `Clients` property of the context and putting it in the `StockTickerClient` property lets you write code to call client methods that looks the same as it would in a `Hub` class. For instance, to broadcast to all clients you can write `Clients.All.updateStockPrice(stock)`.

The `updateStockPrice` method that you're calling in `BroadcastStockPrice` doesn't exist yet. You'll add it later when you write code that runs on the client. You can refer to `updateStockPrice` here because `Clients.All` is dynamic, which means the app will evaluate the expression at runtime. When this method call executes, SignalR will send the method name and the parameter value to the client, and if the client has a method named `updateStockPrice`, the app will call that method and pass the parameter value to it.

`Clients.All` means send to all clients. SignalR gives you other options to specify which clients or groups of clients to send to. For more information, see HubConnectionContext.

Register the SignalR route

The server needs to know which URL to intercept and direct to SignalR. To do that, add an OWIN startup class:

1. In **Solution Explorer**, right-click the project and select **Add** > **New Item**.
2. In **Add New Item - SignalR.StockTicker** select **Installed** > **Visual C#** > **Web** and then select **OWIN Startup Class**.
3. Name the class *Startup* and select **OK**.
4. Replace the default code in the *Startup.cs* file with this code:

```
using System;
using System.Threading.Tasks;
using Microsoft.Owin;
using Owin;

[assembly: OwinStartup(typeof(SignalR.StockTicker.Startup))]

namespace SignalR.StockTicker
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            // Any connection or hub wire up and configuration should go here
            app.MapSignalR();
        }

    }
}
```

You have now finished setting up the server code. In the next section, you'll set up the client.

Set up the client code

In this section, you set up the code that runs on the client.

Create the HTML page and JavaScript file

The HTML page will display the data and the JavaScript file will organize the data.

Create StockTicker.html

First, you'll add the HTML client.

1. In **Solution Explorer**, right-click the project and select **Add** > **HTML Page**.
2. Name the file *StockTicker* and select **OK**.
3. Replace the default code in the *StockTicker.html* file with this code:

```
<!DOCTYPE html>
<html xmlns="http://www.w3.org/1999/xhtml">
<head>
    <title>ASP.NET SignalR Stock Ticker</title>
    <style>
        body {
            font-family: 'Segoe UI', Arial, Helvetica, sans-serif;
            font-size: 16px;
        }
        #stockTable table {
            border-collapse: collapse;
        }
            #stockTable table th, #stockTable table td {
                padding: 2px 6px;
            }
            #stockTable table td {
                text-align: right;
            }
        #stockTable .loading td {
            text-align: left;
        }
    </style>
</head>
<body>
    <h1>ASP.NET SignalR Stock Ticker Sample</h1>

    <h2>Live Stock Table</h2>
    <div id="stockTable">
        <table border="1">
            <thead>
                <tr><th>Symbol</th><th>Price</th><th>Open</th><th>Change</th><th>%</th></tr>
            </thead>
            <tbody>
                <tr class="loading"><td colspan="5">loading...</td></tr>
            </tbody>
        </table>
    </div>

    <!--Script references. -->
    <!--Reference the jQuery library. -->
    <script src="/Scripts/jquery-1.10.2.min.js" ></script>
    <!--Reference the SignalR library. -->
    <script src="/Scripts/jquery.signalR-2.1.0.js"></script>
    <!--Reference the autogenerated SignalR hub script. -->
    <script src="/signalr/hubs"></script>
    <!--Reference the StockTicker script. -->
    <script src="StockTicker.js"></script>
</body>
</html>
```

The HTML creates a table with five columns, a header row, and a data row with a single cell that spans all five columns. The data row shows "loading..." momentarily when the app starts. JavaScript code will remove that row and add in its place rows with stock data retrieved from the server.

The script tags specify:

- The jQuery script file.
- The SignalR core script file.
- The SignalR proxies script file.
- A StockTicker script file that you'll create later.

The app dynamically generates the SignalR proxies script file. It specifies the "/signalr/hubs" URL and

defines proxy methods for the methods on the Hub class, in this case, for `StockTickerHub.GetAllStocks`. If you prefer, you can generate this JavaScript file manually by using SignalR Utilities. Don't forget to disable dynamic file creation in the `MapHubs` method call.

4. In **Solution Explorer**, expand **Scripts**.

   Script libraries for jQuery and SignalR are visible in the project.

   > **IMPORTANT**
   >
   > The package manager will install a later version of the SignalR scripts.

5. Update the script references in the code block to correspond to the versions of the script files in the project.

6. In **Solution Explorer**, right-click *StockTicker.html*, and then select **Set as Start Page**.

Create StockTicker.js

Now create the JavaScript file.

1. In **Solution Explorer**, right-click the project and select **Add** > **JavaScript File**.

2. Name the file *StockTicker* and select **OK**.

3. Add this code to the *StockTicker.js* file:

```
// A simple templating method for replacing placeholders enclosed in curly braces.
if (!String.prototype.supplant) {
    String.prototype.supplant = function (o) {
        return this.replace(/{([^{}]*)}/g,
            function (a, b) {
                var r = o[b];
                return typeof r === 'string' || typeof r === 'number' ? r : a;
            }
        );
    };
}

$(function () {

    var ticker = $.connection.stockTickerMini, // the generated client-side hub proxy
        up = '▲',
        down = '▼',
        $stockTable = $('#stockTable'),
        $stockTableBody = $stockTable.find('tbody'),
        rowTemplate = '<tr data-symbol="{Symbol}"><td>{Symbol}</td><td>{Price}</td><td>{DayOpen}</td>
<td>{Direction} {Change}</td><td>{PercentChange}</td></tr>';

    function formatStock(stock) {
        return $.extend(stock, {
            Price: stock.Price.toFixed(2),
            PercentChange: (stock.PercentChange * 100).toFixed(2) + '%',
            Direction: stock.Change === 0 ? '' : stock.Change >= 0 ? up : down
        });
    }

    function init() {
        ticker.server.getAllStocks().done(function (stocks) {
            $stockTableBody.empty();
            $.each(stocks, function () {
                var stock = formatStock(this);
                $stockTableBody.append(rowTemplate.supplant(stock));
            });
        });
    }

    // Add a client-side hub method that the server will call
    ticker.client.updateStockPrice = function (stock) {
        var displayStock = formatStock(stock),
            $row = $(rowTemplate.supplant(displayStock));

        $stockTableBody.find('tr[data-symbol=' + stock.Symbol + ']')
            .replaceWith($row);
        }

    // Start the connection
    $.connection.hub.start().done(init);

});
```

Examine the client code

If you examine the client code, it will help you learn how the client code interacts with the server code to make the app work.

Starting the connection

`$.connection` refers to the SignalR proxies. The code gets a reference to the proxy for the `StockTickerHub` class and puts it in the `ticker` variable. The proxy name is the name that was set by the `HubName` attribute:

```
var ticker = $.connection.stockTickerMini
```

```
[HubName("stockTickerMini")]
public class StockTickerHub : Hub
```

After you define all the variables and functions, the last line of code in the file initializes the SignalR connection by calling the SignalR `start` function. The `start` function executes asynchronously and returns a jQuery Deferred object. You can call the done function to specify the function to call when the app finishes the asynchronous action.

```
$.connection.hub.start().done(init);
```

Getting all the stocks

The `init` function calls the `getAllStocks` function on the server and uses the information that the server returns to update the stock table. Notice that, by default, you have to use camelCasing on the client even though the method name is pascal-cased on the server. The camelCasing rule only applies to methods, not objects. For example, you refer to `stock.Symbol` and `stock.Price`, not `stock.symbol` or `stock.price`.

```
function init() {
    ticker.server.getAllStocks().done(function (stocks) {
        $stockTableBody.empty();
        $.each(stocks, function () {
            var stock = formatStock(this);
            $stockTableBody.append(rowTemplate.supplant(stock));
        });
    });
}
```

```
public IEnumerable<Stock> GetAllStocks()
{
    return _stockTicker.GetAllStocks();
}
```

In the `init` method, the app creates HTML for a table row for each stock object received from the server by calling `formatStock` to format properties of the `stock` object, and then by calling `supplant` to replace placeholders in the `rowTemplate` variable with the `stock` object property values. The resulting HTML is then appended to the stock table.

> **NOTE**
> You call `init` by passing it in as a `callback` function that executes after the asynchronous `start` function finishes. If you called `init` as a separate JavaScript statement after calling `start`, the function would fail because it would run immediately without waiting for the start function to finish establishing the connection. In that case, the `init` function would try to call the `getAllStocks` function before the app establishes a server connection.

Getting updated stock prices

When the server changes a stock's price, it calls the `updateStockPrice` on connected clients. The app adds the function to the client property of the `stockTicker` proxy to make it available to calls from the server.

```
ticker.client.updateStockPrice = function (stock) {
    var displayStock = formatStock(stock),
        $row = $(rowTemplate.supplant(displayStock));

    $stockTableBody.find('tr[data-symbol=' + stock.Symbol + ']')
        .replaceWith($row);
    }
```

The `updateStockPrice` function formats a stock object received from the server into a table row the same way as in the `init` function. Instead of appending the row to the table, it finds the stock's current row in the table and replaces that row with the new one.

Test the application

You can test the app to make sure it's working. You'll see all browser windows display the live stock table with stock prices fluctuating.

1. In the toolbar, turn on **Script Debugging** and then select the play button to run the app in Debug mode.

   A browser window will open displaying the **Live Stock Table**. The stock table initially shows the "loading..." line, then, after a short time, the app shows the initial stock data, and then the stock prices start to change.

2. Copy the URL from the browser, open two other browsers, and paste the URLs into the address bars.

   The initial stock display is the same as the first browser and changes happen simultaneously.

3. Close all browsers, open a new browser, and go to the same URL.

   The StockTicker singleton object continued to run in the server. The **Live Stock Table** shows that the stocks have continued to change. You don't see the initial table with zero change figures.

4. Close the browser.

Enable logging

SignalR has a built-in logging function that you can enable on the client to aid in troubleshooting. In this section, you enable logging and see examples that show how logs tell you which of the following transport methods SignalR is using:

- WebSockets, supported by IIS 8 and current browsers.
- Server-sent events, supported by browsers other than Internet Explorer.
- Forever frame, supported by Internet Explorer.
- Ajax long polling, supported by all browsers.

For any given connection, SignalR chooses the best transport method that both the server and the client support.

1. Open *StockTicker.js*.
2. Add this highlighted line of code to enable logging immediately before the code that initializes the

connection at the end of the file:

```
// Start the connection
$.connection.hub.logging = true;
$.connection.hub.start().done(init);
```

3. Press **F5** to run the project.

4. Open your browser's developer tools window, and select the Console to see the logs. You might have to refresh the page to see the logs of SignalR negotiating the transport method for a new connection.

   - If you're running Internet Explorer 10 on Windows 8 (IIS 8), the transport method is **WebSockets**.
   - If you're running Internet Explorer 10 on Windows 7 (IIS 7.5), the transport method is **iframe**.
   - If you're running Firefox 19 on Windows 8 (IIS 8), the transport method is **WebSockets**.

     > **TIP**
     > In Firefox, install the Firebug add-in to get a Console window.

   - If you're running Firefox 19 on Windows 7 (IIS 7.5), the transport method is **server-sent** events.

Install the StockTicker sample

The Microsoft.AspNet.SignalR.Sample installs the StockTicker application. The NuGet package includes more features than the simplified version that you created from scratch. In this section of the tutorial, you install the NuGet package and review the new features and the code that implements them.

> **IMPORTANT**
> If you install the package without performing the earlier steps of this tutorial, you must add an OWIN startup class to your project. This readme.txt file for the NuGet package explains this step.

Install the SignalR.Sample NuGet package

1. In **Solution Explorer**, right-click the project and select **Manage NuGet Packages**.

2. In **NuGet Package manager: SignalR.StockTicker**, select **Browse**.

3. From **Package source**, select **nuget.org**.

4. Enter *SignalR.Sample* in the search box and select **Microsoft.AspNet.SignalR.Sample** > **Install**.

5. In **Solution Explorer**, expand the *SignalR.Sample* folder.

   Installing the SignalR.Sample package created the folder and its contents.

6. In the *SignalR.Sample* folder, right-click *StockTicker.html*, and then select **Set As Start Page**.

   > **NOTE**
   > Installing The SignalR.Sample NuGet package might change the version of jQuery that you have in your *Scripts* folder. The new *StockTicker.html* file that the package installs in the *SignalR.Sample* folder will be in sync with the jQuery version that the package installs, but if you want to run your original *StockTicker.html* file again, you might have to update the jQuery reference in the script tag first.

Run the application

The table that you saw in the first app had useful features. The full stock ticker application shows new features: a horizontally scrolling window that shows the stock data and stocks that change color as they rise and fall.

1. Press **F5** to run the app.

   When you run the app for the first time, the "market" is "closed" and you see a static table and a ticker window that isn't scrolling.

2. Select **Open Market**.

   - The **Live Stock Ticker** box starts to scroll horizontally, and the server starts to periodically broadcast stock price changes on a random basis.
   - Each time a stock price changes, the app updates both the **Live Stock Table** and the **Live Stock Ticker**.
   - When a stock's price change is positive, the app shows the stock with a green background.
   - When the change is negative, the app shows the stock with a red background.

3. Select **Close Market**.
   - The table updates stop.
   - The ticker stops scrolling.

4. Select **Reset**.
   - All stock data is reset.
   - The app restores the initial state before price changes started.

5. Copy the URL from the browser, open two other browsers, and paste the URLs into the address bars.

6. You see the same data dynamically updated at the same time in each browser.

7. When you select any of the controls, all browsers respond the same way at the same time.

Live Stock Ticker display

The **Live Stock Ticker** display is an unordered list in a `<div>` element formatted into a single line by CSS styles. The app initializes and updates the ticker the same way as the table: by replacing placeholders in an `<li>` template string and dynamically adding the `<li>` elements to the `<ul>` element. The app includes scrolling by using the jQuery `animate` function to vary the margin-left of the unordered list within the `<div>`.

SignalR.Sample StockTicker.html

The stock ticker HTML code:

```
<h2>Live Stock Ticker</h2>
<div id="stockTicker">
    <div class="inner">
        <ul>
            <li class="loading">loading...</li>
        </ul>
    </div>
</div>
```

SignalR.Sample StockTicker.css

The stock ticker CSS code:

```
#stockTicker {
    overflow: hidden;
    width: 450px;
    height: 24px;
    border: 1px solid #999;
    }

    #stockTicker .inner {
        width: 9999px;
    }

    #stockTicker ul {
        display: inline-block;
        list-style-type: none;
        margin: 0;
        padding: 0;
    }

    #stockTicker li {
        display: inline-block;
        margin-right: 8px;
    }

    /*<li data-symbol="{Symbol}"><span class="symbol">{Symbol}</span><span class="price">{Price}</span><span
class="change">{PercentChange}</span></li>*/
    #stockTicker .symbol {
        font-weight: bold;
    }

    #stockTicker .change {
        font-style: italic;
    }
```

SignalR.Sample SignalR.StockTicker.js

The jQuery code that makes it scroll:

```
function scrollTicker() {
    var w = $stockTickerUl.width();
    $stockTickerUl.css({ marginLeft: w });
    $stockTickerUl.animate({ marginLeft: -w }, 15000, 'linear', scrollTicker);
}
```

Additional methods on the server that the client can call

To add flexibility to the app, there are additional methods the app can call.

SignalR.Sample StockTickerHub.cs

The `StockTickerHub` class defines four additional methods that the client can call:

```
public string GetMarketState()
{
    return _stockTicker.MarketState.ToString();
}

public void OpenMarket()
{
    _stockTicker.OpenMarket();
}

public void CloseMarket()
{
    _stockTicker.CloseMarket();
}

public void Reset()
{
    _stockTicker.Reset();
}
```

The app calls `OpenMarket`, `CloseMarket`, and `Reset` in response to the buttons at the top of the page. They demonstrate the pattern of one client triggering a change in state immediately propagated to all clients. Each of these methods calls a method in the `StockTicker` class that causes the market state change and then broadcasts the new state.

SignalR.Sample StockTicker.cs

In the `StockTicker` class, the app maintains the state of the market with a `MarketState` property that returns a `MarketState` enum value:

```
public MarketState MarketState
{
    get { return _marketState; }
    private set { _marketState = value; }
}

public enum MarketState
{
    Closed,
    Open
}
```

Each of the methods that change the market state do so inside a lock block because the `StockTicker` class has to be thread-safe:

```
public void OpenMarket()
{
    lock (_marketStateLock)
    {
        if (MarketState != MarketState.Open)
        {
            _timer = new Timer(UpdateStockPrices, null, _updateInterval, _updateInterval);
            MarketState = MarketState.Open;
            BroadcastMarketStateChange(MarketState.Open);
        }
    }
}

public void CloseMarket()
{
    lock (_marketStateLock)
    {
        if (MarketState == MarketState.Open)
        {
            if (_timer != null)
            {
                _timer.Dispose();
            }
            MarketState = MarketState.Closed;
            BroadcastMarketStateChange(MarketState.Closed);
        }
    }
}

public void Reset()
{
    lock (_marketStateLock)
    {
        if (MarketState != MarketState.Closed)
        {
            throw new InvalidOperationException("Market must be closed before it can be reset.");
        }
        LoadDefaultStocks();
        BroadcastMarketReset();
    }
}
```

To make sure this code is thread-safe, the `_marketState` field that backs the `MarketState` property designated `volatile`:

```
private volatile MarketState _marketState;
```

The `BroadcastMarketStateChange` and `BroadcastMarketReset` methods are similar to the BroadcastStockPrice method that you already saw, except they call different methods defined at the client:

```
private void BroadcastMarketStateChange(MarketState marketState)
{
    switch (marketState)
    {
        case MarketState.Open:
            Clients.All.marketOpened();
            break;
        case MarketState.Closed:
            Clients.All.marketClosed();
            break;
        default:
            break;
    }
}

private void BroadcastMarketReset()
{
    Clients.All.marketReset();
}
```

Additional functions on the client that the server can call

The `updateStockPrice` function now handles both the table and the ticker display, and it uses `jQuery.Color` to flash red and green colors.

New functions in *SignalR.StockTicker.js* enable and disable the buttons based on market state. They also stop or start the **Live Stock Ticker** horizontal scrolling. Since many functions are being added to `ticker.client`, the app uses the jQuery extend function to add them.

```
$.extend(ticker.client, {
    updateStockPrice: function (stock) {
        var displayStock = formatStock(stock),
            $row = $(rowTemplate.supplant(displayStock)),
            $li = $(liTemplate.supplant(displayStock)),
            bg = stock.LastChange === 0
                ? '255,216,0' // yellow
                : stock.LastChange > 0
                    ? '154,240,117' // green
                    : '255,148,148'; // red

        $stockTableBody.find('tr[data-symbol=' + stock.Symbol + ']')
            .replaceWith($row);
        $stockTickerUl.find('li[data-symbol=' + stock.Symbol + ']')
            .replaceWith($li);

        $row.flash(bg, 1000);
        $li.flash(bg, 1000);
    },

    marketOpened: function () {
        $("#open").prop("disabled", true);
        $("#close").prop("disabled", false);
        $("#reset").prop("disabled", true);
        scrollTicker();
    },

    marketClosed: function () {
        $("#open").prop("disabled", false);
        $("#close").prop("disabled", true);
        $("#reset").prop("disabled", false);
        stopTicker();
    },

    marketReset: function () {
        return init();
    }
});
```

Additional client setup after establishing the connection

After the client establishes the connection, it has some additional work to do:

- Find out if the market is open or closed to call the appropriate `marketOpened` or `marketClosed` function.
- Attach the server method calls to the buttons.

```
$.connection.hub.start()
    .pipe(init)
    .pipe(function () {
        return ticker.server.getMarketState();
    })
    .done(function (state) {
        if (state === 'Open') {
            ticker.client.marketOpened();
        } else {
            ticker.client.marketClosed();
        }

        // Wire up the buttons
        $("#open").click(function () {
            ticker.server.openMarket();
        });

        $("#close").click(function () {
            ticker.server.closeMarket();
        });

        $("#reset").click(function () {
            ticker.server.reset();
        });
    });
```

The server methods aren't wired up to the buttons until after the app establishes the connection. It's so the code can't call the server methods before they're available.

Additional resources

In this tutorial you've learned how to program a SignalR application that broadcasts messages from the server to all connected clients. Now you can broadcast messages on a periodic basis and in response to notifications from any client. You can use the concept of multi-threaded singleton instance to maintain server state in multi-player online game scenarios. For an example, see the ShootR game based on SignalR.

For tutorials that show peer-to-peer communication scenarios, see Getting Started with SignalR and Real-Time Updating with SignalR.

For more about SignalR, see the following resources:

- ASP.NET SignalR
- SignalR Project
- SignalR GitHub and Samples
- SignalR Wiki

Next steps

In this tutorial, you:

- Created the project
- Set up the server code
- Examined the server code
- Set up the client code
- Examined the client code
- Tested the application
- Enabled logging

Advance to the next article to learn how to create a real-time web application that uses ASP.NET SignalR 2.

Create real-time web app with SignalR

Hands On Lab: Real-Time Web Applications with SignalR

2/20/2020 • 17 minutes to read • Edit Online

by Web Camps Team

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

Download Web Camps Training Kit, October 2015 Release

Real-time Web applications feature the ability to push server-side content to the connected clients as it happens, in real-time. For ASP.NET developers, **ASP.NET SignalR** is a library to add real-time web functionality to their applications. It takes advantage of several transports, automatically selecting the best available transport given the client and server's best available transport. It takes advantage of **WebSocket**, an HTML5 API that enables bi-directional communication between the browser and server.

SignalR also provides a simple, high-level API for doing server to client RPC (call JavaScript functions in your clients' browsers from server-side .NET code) in your ASP.NET application, as well as adding useful hooks for connection management, such as connect/disconnect events, grouping connections, and authorization.

SignalR is an abstraction over some of the transports that are required to do real-time work between client and server. A **SignalR** connection starts as HTTP, and is then promoted to a **WebSocket** connection if available. **WebSocket** is the ideal transport for **SignalR**, since it makes the most efficient use of server memory, has the lowest latency, and has the most underlying features (such as full duplex communication between client and server), but it also has the most stringent requirements: **WebSocket** requires the server to be using **Windows Server 2012** or **Windows 8**, along with **.NET Framework 4.5**. If these requirements are not met, **SignalR** will attempt to use other transports to make its connections (like *Ajax long polling*).

The **SignalR** API contains two models for communicating between clients and servers: **Persistent Connections** and **Hubs**. A **Connection** represents a simple endpoint for sending single-recipient, grouped, or broadcast messages. A **Hub** is a more high-level pipeline built upon the Connection API that allows your client and server to call methods on each other directly.

All sample code and snippets are included in the Web Camps Training Kit, October 2015 Release, available at

> https://github.com/Microsoft-Web/WebCampTrainingKit/releases/tag/v2015.10.13b. Please note that the Installer link on that page no longer works; use one of the links under the Assets section instead.

Overview

Objectives

In this hands-on lab, you will learn how to:

- Send notifications from server to client using SignalR.
- Scale Out your SignalR application using **SQL Server**.

Prerequisites

The following is required to complete this hands-on lab:

- Visual Studio Express 2013 for Web or greater

Setup

In order to run the exercises in this hands-on lab, you will need to set up your environment first.

1. Open a Windows Explorer window and browse to the lab's **Source** folder.
2. Right-click **Setup.cmd** and select **Run as administrator** to launch the setup process that will configure your environment and install the Visual Studio code snippets for this lab.
3. If the User Account Control dialog box is shown, confirm the action to proceed.

> **NOTE**
> Make sure you have checked all the dependencies for this lab before running the setup.

Using the Code Snippets

Throughout the lab document, you will be instructed to insert code blocks. For your convenience, most of this code is provided as Visual Studio Code Snippets, which you can access from within Visual Studio 2013 to avoid having to add it manually.

> **NOTE**
> Each exercise is accompanied by a starting solution located in the **Begin** folder of the exercise that allows you to follow each exercise independently of the others. Please be aware that the code snippets that are added during an exercise are missing from these starting solutions and may not work until you have completed the exercise. Inside the source code for an exercise, you will also find an **End** folder containing a Visual Studio solution with the code that results from completing the steps in the corresponding exercise. You can use these solutions as guidance if you need additional help as you work through this hands-on lab.

Exercises

This hands-on lab includes the following exercises:

1. Working with Real-Time Data Using SignalR
2. Scaling Out Using SQL Server

Estimated time to complete this lab: **60 minutes**

> **NOTE**
> When you first start Visual Studio, you must select one of the predefined settings collections. Each predefined collection is designed to match a particular development style and determines window layouts, editor behavior, IntelliSense code snippets, and dialog box options. The procedures in this lab describe the actions necessary to accomplish a given task in Visual Studio when using the **General Development Settings** collection. If you choose a different settings collection for your development environment, there may be differences in the steps that you should take into account.

Exercise 1: Working with Real-Time Data Using SignalR

While chat is often used as an example, you can do a whole lot more with real-time Web functionality. Any time a user refreshes a web page to see new data or the page implements Ajax long polling to retrieve new data, you can use SignalR.

SignalR supports **server push** or **broadcasting** functionality; it handles connection management automatically. In classic HTTP connections for client-server communication, connection is re-established for each request, but SignalR provides persistent connection between the client and server. In SignalR the server code calls out to a client code in the browser using Remote Procedure Calls (RPC), rather than the request-response model we know today.

In this exercise, you will configure the **Geek Quiz** application to use SignalR to display the Statistics dashboard with the updated metrics without the need to refresh the entire page.

Task 1 – Exploring the Geek Quiz Statistics Page

In this task, you will go through the application and verify how the statistics page is shown and how you can improve the way the information is updated.

1. Open **Visual Studio Express 2013 for Web** and open the **GeekQuiz.sln** solution located in the **Source\Ex1-WorkingWithRealTimeData\Begin** folder.
2. Press **F5** to run the solution. The **Log in** page should appear in the browser.

Running the solution

3. Click **Register** in the upper-right corner of the page to create a new user in the application.

Register link

4. In the **Register** page, enter a **User name** and **Password**, and then click **Register**.

Registering a user

5. The application registers the new account and the user is authenticated and redirected back to the home page showing the first quiz question.

6. Open the **Statistics** page in a new window and put the **Home** page and **Statistics** page side-by-side.

Side-by-side windows

7. In the **Home** page, answer the question by clicking one of the options.

Answering a question

8. After clicking one of the buttons, the answer should appear.

Question answered correctly

9. Notice that the information provided in the Statistics page is outdated. Refresh the page in order to see the updated results.

Statistics page

10. Go back to Visual Studio and stop debugging.

Task 2 – Adding SignalR to Geek Quiz to Show Online Charts

In this task, you will add SignalR to the solution and send updates to the clients automatically when a new answer is sent to the server.

1. From the **Tools** menu in Visual Studio, select **NuGet Package Manager**, and then click **Package Manager Console**.

2. In the **Package Manager Console** window, execute the following command:

```
Install-Package Microsoft.AspNet.SignalR
```

SignalR package installation

> **NOTE**
>
> When installing **SignalR** NuGet packages version 2.0.2 from a brand new MVC 5 application, you will need to manually update **OWIN** packages to version 2.0.1 (or higher) before installing SignalR. To do this, you can execute the following script in the **Package Manager Console**:
>
> ```
> get-package | where-object { $_.Id -like "Microsoft.Owin*"} | Update-Package
> ```
>
> In a future release of SignalR, OWIN dependencies will be automatically updated.

3. In **Solution Explorer**, expand the **Scripts** folder and notice that the SignalR *js* files were added to the solution.

SignalR JavaScript references

4. In **Solution Explorer**, right-click the **GeekQuiz** project, select **Add | New Folder**, and name it **Hubs**.

5. Right-click the **Hubs** folder and select **Add | New Item**.

Add new item

6. In the **Add New Item** dialog box, select the **Visual C# | Web | SignalR** node in the left pane, select **SignalR Hub Class (v2)** from the center pane, name the file **StatisticsHub.cs** and click **Add**.

Add new item dialog box

7. Replace the code in the **StatisticsHub** class with the following code.

(Code Snippet - *RealTimeSignalR - Ex1 - StatisticsHubClass*)

```
namespace GeekQuiz.Hubs
{
    using Microsoft.AspNet.SignalR;

    public class StatisticsHub : Hub
    {
    }
}
```

8. Open **Startup.cs** and add the following line at the end of the **Configuration** method.

   (Code Snippet - *RealTimeSignalR - Ex1 - MapSignalR*)

```
public void Configuration(IAppBuilder app)
{
    this.ConfigureAuth(app);
    app.MapSignalR();
}
```

9. Open the **StatisticsService.cs** page inside the **Services** folder and add the following using directives.

   (Code Snippet - *RealTimeSignalR - Ex1 - UsingDirectives*)

```
using Microsoft.AspNet.SignalR;
using GeekQuiz.Hubs;
```

10. To notify connected clients of updates, you first retrieve a **Context** object for the current connection. The **Hub** object contains methods to send messages to a single client or broadcast to all connected clients. Add the following method to the **StatisticsService** class to broadcast the statistics data.

    (Code Snippet - *RealTimeSignalR - Ex1 - NotifyUpdatesMethod*)

```
public async Task NotifyUpdates()
{
    var hubContext = GlobalHost.ConnectionManager.GetHubContext<StatisticsHub>();
    if (hubContext != null)
    {
         var stats = await this.GenerateStatistics();
         hubContext.Clients.All.updateStatistics(stats);
    }
}
```

> **NOTE**
>
> In the code above, you are using an arbitrary method name to call a function on the client (i.e.: *updateStatistics*). The method name that you specify is interpreted as a dynamic object, which means there is no IntelliSense or compile-time validation for it. The expression is evaluated at run time. When the method call executes, SignalR sends the method name and the parameter values to the client. If the client has a method that matches the name, that method is called and the parameter values are passed to it. If no matching method is found on the client, no error is raised. For more information, refer to ASP.NET SignalR Hubs API Guide.

11. Open the **TriviaController.cs** page inside the **Controllers** folder and add the following using directives.

```
using GeekQuiz.Services;
```

12. Add the following highlighted code to the **Post** action method.

    (Code Snippet - *RealTimeSignalR - Ex1 - NotifyUpdatesCall*)

```
public async Task<IHttpActionResult> Post(TriviaAnswer answer)
{
    if (!ModelState.IsValid)
    {
         return this.BadRequest(this.ModelState);
    }

    answer.UserId = User.Identity.Name;

    var isCorrect = await this.StoreAsync(answer);

    var statisticsService = new StatisticsService(this.db);
    await statisticsService.NotifyUpdates();

    return this.Ok<bool>(isCorrect);
}
```

13. Open the **Statistics.cshtml** page inside the **Views | Home** folder. Locate the **Scripts** section and add the following script references at the beginning of the section.

    (Code Snippet - *RealTimeSignalR - Ex1 - SignalRScriptReferences*)

```
@section Scripts {
    @Scripts.Render("~/Scripts/jquery.signalR-2.0.2.min.js");
    @Scripts.Render("~/signalr/hubs");
    ...
}
```

> **NOTE**
> When you add SignalR and other script libraries to your Visual Studio project, the Package Manager might install a version of the SignalR script file that is more recent than the version shown in this topic. Make sure that the script reference in your code matches the version of the script library installed in your project.

14. Add the following highlighted code to connect the client to the SignalR hub and update the statistics data when a new message is received from the hub.

    (Code Snippet - *RealTimeSignalR - Ex1 - SignalRClientCode*)

```
@section Scripts {
    ...
    <script>
        ...

        var connection = $.hubConnection();
        var hub = connection.createHubProxy("StatisticsHub");
        hub.on("updateStatistics", function (statistics) {
                statisticsData = statistics;
                $("#correctAnswersCounter").text(statistics.CorrectAnswers);
                $("#incorrectAnswersCounter").text(statistics.IncorrectAnswers);

                showCharts(statisticsData);
          });

        connection.start();
    </script>
}
```

In this code, you are creating a Hub Proxy and registering an event handler to listen for messages sent by

the server. In this case, you listen for messages sent through the *updateStatistics* method.

Task 3 – Running the Solution

In this task, you will run the solution to verify that the statistics view is updated automatically using SignalR after answering a new question.

1. Press **F5** to run the solution.

> **NOTE**
>
> If not already logged in to the application, log in with the user you created in Task 1.

2. Open the **Statistics** page in a new window and put the **Home** page and **Statistics** page side-by-side as you did in Task 1.

3. In the **Home** page, answer the question by clicking one of the options.

Answering another question

4. After clicking one of the buttons, the answer should appear. Notice that the Statistics information on the page is updated automatically after answering the question with the updated information without the need to refresh the entire page.

Statistics page refreshed after answer

Exercise 2: Scaling Out Using SQL Server

When scaling a web application, you can generally choose between *scaling up* and *scaling out* options. *Scale up* means using a larger server, with more resources (CPU, RAM, etc.) while *scale out* means adding more servers to

handle the load. The problem with the latter is that the clients can get routed to different servers. A client that is connected to one server will not receive messages sent from another server.

You can solve these issues by using a component called *backplane*, to forward messages between servers. With a backplane enabled, each application instance sends messages to the backplane, and the backplane forwards them to the other application instances.

There are currently three types of backplanes for SignalR:

- **Windows Azure Service Bus**. Service Bus is a messaging infrastructure that allows components to send loosely coupled messages.
- **SQL Server**. The SQL Server backplane writes messages to SQL tables. The backplane uses Service Broker for efficient messaging. However, it also works if Service Broker is not enabled.
- **Redis**. Redis is an in-memory key-value store. Redis supports a publish/subscribe ("pub/sub") pattern for sending messages.

Every message is sent through a message bus. A message bus implements the IMessageBus interface, which provides a publish/subscribe abstraction. The backplanes work by replacing the default **IMessageBus** with a bus designed for that backplane.

Each server instance connects to the backplane through the bus. When a message is sent, it goes to the backplane, and the backplane sends it to every server. When a server receives a message from the backplane, it stores the message in its local cache. The server then delivers messages to clients from its local cache.

For more information about how the SignalR backplane works, read this article.

> **NOTE**
>
> There are some scenarios where a backplane can become a bottleneck. Here are some typical SignalR scenarios:
>
> - Server broadcast (e.g., stock ticker): Backplanes work well for this scenario, because the server controls the rate at which messages are sent.
> - Client-to-client (e.g., chat): In this scenario, the backplane might be a bottleneck if the number of messages scales with the number of clients; that is, if the rate of messages grows proportionally as more clients join.
> - High-frequency realtime (e.g., real-time games): A backplane is not recommended for this scenario.

In this exercise, you will use **SQL Server** to distribute messages across the **Geek Quiz** application. You will run these tasks on a single test machine to learn how to set up the configuration, but in order to get the full effect, you will need to deploy the SignalR application to two or more servers. You must also install SQL Server on one of the servers, or on a separate dedicated server.

Task 1 - Understanding the Scenario

In this task, you will run 2 instances of **Geek Quiz** simulating multiple IIS instances on your local machine. In this

scenario, when answering trivia questions on one application, update won't be notified on the statistics page of the second instance. This simulation resembles an environment where your application is deployed on multiple instances and using a load balancer to communicate with them.

1. Open the **Begin.sln** solution located in the **Source/Ex2-ScalingOutWithSQLServer/Begin** folder. Once loaded, you will notice on the **Server Explorer** that the solution has two projects with identical structures but different names. This will simulate running two instances of the same application on your local machine.

Begin Solution Simulating 2 Instances of Geek Quiz

2. Open the properties page of the solution by right-clicking the solution node and selecting **Properties**. Under **Startup Project**, select **Multiple startup projects** and change the **Action** value for both projects to *Start*.

Starting Multiple Projects

3. Press **F5** to run the solution. The application will launch two instances of **Geek Quiz** in different ports, simulating multiple instances of the same application. Pin one of the browsers on left and the other on the right of your screen. Log in with your credentials or register a new user. Once logged in, keep the Trivia page on the left and go to the **Statistics** page in the browser on the right.

Geek Quiz Side by Side

Geek Quiz in Different Ports

4. Start answering questions in the left browser and you will notice that the **Statistics** page in the right browser is not being updated. This is because **SignalR** uses a local cache to distribute messages across their clients and this scenario is simulating multiple instances, therefore the cache is not shared between them. You can verify that **SignalR** is working by testing the same steps but using a single app. In the following tasks you will configure a backplane to replicate the messages across instances.

5. Go back to Visual Studio and stop debugging.

Task 2 – Creating the SQL Server Backplane

In this task, you will create a database that will serve as a backplane for the **Geek Quiz** application. You will use **SQL Server Object Explorer** to browse your server and initialize the database. Additionally, you will enable the **Service Broker**.

1. In **Visual Studio**, open menu **View** and select **SQL Server Object Explorer**.

2. Connect to your LocalDB instance by right-clicking the **SQL Server** node and selecting **Add SQL Server...** option.

Adding a SQL Server instance to SQL Server Object Explorer

3. Set the **server name** to *(localdb)\v11.0* and leave **Windows Authentication** as your authentication mode. Click **Connect** to continue.

Connecting to LocalDB

4. Now that you are connected to your LocalDB instance, you will need to create a database that will represent the SQL Server backplane for SignalR. To do this, right-click the **Databases** node and select **Add New Database**.

Adding a new database

5. Set the database name to *SignalR* and click **OK** to create it.

Creating the SignalR database

> **NOTE**
>
> You can choose any name for the database.

6. To receive updates more efficiently from the backplane, it is recommended to enable Service Broker for the database. Service Broker provides native support for messaging and queuing in SQL Server. The backplane also works without Service Broker. Open a new query by right-clicking the database and select **New Query**.

Opening a New Query

7. To check whether Service Broker is enabled, query the **is_broker_enabled** column in the **sys.databases** catalog view. Execute the following script in the recently opened query window.

```
SELECT [name], [service_broker_guid], [is_broker_enabled] FROM [master].[sys].[databases]
```

Querying the Service Broker Status

8. If the value of the **is_broker_enabled** column in your database is "0", use the following command to enable it. Replace **<YOUR-DATABASE>** with the name you set when creating the database (e.g.: SignalR).

```
ALTER DATABASE <YOUR-DATABASE> SET ENABLE_BROKER
```

Enabling Service Broker

> **NOTE**
> If this query appears to deadlock, make sure there are no applications connected to the DB.

Task 3 – Configuring the SignalR Application

In this task, you will configure **Geek Quiz** to connect to the SQL Server backplane. You will first add the **SignalR.SqlServer** NuGet package and set the connection string to your backplane database.

1. Open the **Package Manager Console** from **Tools** > **NuGet Package Manager**. Make sure that **GeekQuiz** project is selected in the **Default project** drop-down list. Type the following command to install the **Microsoft.AspNet.SignalR.SqlServer** NuGet package.

```
Install-Package Microsoft.AspNet.SignalR.SqlServer
```

2. Repeat the previous step but this time for project **GeekQuiz2**.

3. To configure the SQL Server backplane, open the **Startup.cs** file of the **GeekQuiz** project and add the following code to the **Configure** method. Replace **<YOUR-DATABASE>** with your database name you used when creating the SQL Server backplane. Repeat this step for the **GeekQuiz2** project.

   (Code Snippet - *RealTimeSignalR - Ex2 - StartupConfiguration*)

```
public class Startup
{
    public void Configuration(IAppBuilder app)
    {
        var sqlConnectionString = @"Server=(localdb)\v11.0;Database=<YOUR-DATABASE>;Integrated
Security=True;";
        GlobalHost.DependencyResolver.UseSqlServer(sqlConnectionString);
        this.ConfigureAuth(app);
        app.MapSignalR();
    }
}
```

4. Now that both projects are configured to use the SQL Server backplane, press **F5** to run them simultaneously.

5. Again, **Visual Studio** will launch two instances of **Geek Quiz** in different ports. Pin one of the browsers on the left and the other on the right of your screen and log in with your credentials. Keep the Trivia page on the left and go to **Statistics** pagein the right browser.

6. Start answering questions in the left browser. This time, the **Statistics** page is updated thanks to the backplane. Switch between applications (**Statistics** is now on the left, and **Trivia** is on the right) and repeat the test to validate that it is working for both instances. The backplane serves as a *shared cache* of messages for each connected server, and each server will store the messages in their own local cache to distribute to connected clients.

7. Go back to Visual Studio and stop debugging.

8. The SQL Server backplane component automatically generates the necessary tables on the specified database. In the **SQL Server Object Explorer** panel, open the database you created for the backplane (e.g.: SignalR) and expand its tables. You should see the following tables:

Backplane Generated Tables

9. Right-click the **SignalR.Messages_0** table and select **View Data**.

View SignalR Backplane Messages Table

10. You can see the different messages sent to the **Hub** when answering the trivia questions. The backplane distributes these messages to any connected instance.

PayloadId	Payload	InsertedOn
1	<Binary data>	25/02/2014 05:3...
2	<Binary data>	25/02/2014 05:3...
3	<Binary data>	25/02/2014 05:3...

Backplane Messages Table

Summary

In this hands-on lab, you have learned how to add **SignalR** to your application and send notifications from the server to your connected clients using **Hubs**. Additionally, you learned how to scale out your application by using a *backplane* component when your application is deployed in multiple IIS instances.

SignalR Guide to the API

ASP.NET SignalR Hubs API Guide - Server (C#)

2/20/2020 • 32 minutes to read • Edit Online

by Patrick Fletcher, Tom Dykstra

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This document provides an introduction to programming the server side of the ASP.NET SignalR Hubs API for SignalR version 2, with code samples demonstrating common options.

The SignalR Hubs API enables you to make remote procedure calls (RPCs) from a server to connected clients and from clients to the server. In server code, you define methods that can be called by clients, and you call methods that run on the client. In client code, you define methods that can be called from the server, and you call methods that run on the server. SignalR takes care of all of the client-to-server plumbing for you.

SignalR also offers a lower-level API called Persistent Connections. For an introduction to SignalR, Hubs, and Persistent Connections, see Introduction to SignalR 2.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Topic versions

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Overview

This document contains the following sections:

- How to register SignalR middleware
  - The /signalr URL
  - Configuring SignalR options
- How to create and use Hub classes
  - Hub object lifetime
  - Camel-casing of Hub names in JavaScript clients
  - Multiple Hubs
  - Strongly-Typed Hubs

- How to define methods in the Hub class that clients can call
  - Camel-casing of method names in JavaScript clients
  - When to execute asynchronously
  - Defining overloads
  - Reporting progress from hub method invocations
- How to call client methods from the Hub class
  - Selecting which clients will receive the RPC
  - No compile-time validation for method names
  - Case-insensitive method name matching
  - Asynchronous execution
- How to manage group membership from the Hub class
  - Asynchronous execution of Add and Remove methods
  - Group membership persistence
  - Single-user groups
- How to handle connection lifetime events in the Hub class
  - When OnConnected, OnDisconnected, and OnReconnected are called
  - Caller state not populated
- How to get information about the client from the Context property
- How to pass state between clients and the Hub class
- How to handle errors in the Hub class
- How to call client methods and manage groups from outside the Hub class
  - Calling client methods
  - Managing group membership
- How to enable tracing
- How to customize the Hubs pipeline

For documentation on how to program clients, see the following resources:

- SignalR Hubs API Guide - JavaScript Client
- SignalR Hubs API Guide - .NET Client

The server components for SignalR 2 are only available in .NET 4.5. Servers running .NET 4.0 must use SignalR v1.x.

How to register SignalR middleware

To define the route that clients will use to connect to your Hub, call the `MapSignalR` method when the application starts. `MapSignalR` is an extension method for the `OwinExtensions` class. The following example shows how to define the SignalR Hubs route using an OWIN startup class.

```
using Microsoft.Owin;
using Owin;

[assembly: OwinStartup(typeof(MyApplication.Startup))]
namespace MyApplication
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            // Any connection or hub wire up and configuration should go here
            app.MapSignalR();
        }

    }
}
```

If you are adding SignalR functionality to an ASP.NET MVC application, make sure that the SignalR route is added before the other routes. For more information, see Tutorial: Getting Started with SignalR 2 and MVC 5.

The /signalr URL

By default, the route URL which clients will use to connect to your Hub is "/signalr". (Don't confuse this URL with the "/signalr/hubs" URL, which is for the automatically generated JavaScript file. For more information about the generated proxy, see SignalR Hubs API Guide - JavaScript Client - The generated proxy and what it does for you.)

There might be extraordinary circumstances that make this base URL not usable for SignalR; for example, you have a folder in your project named *signalr* and you don't want to change the name. In that case, you can change the base URL, as shown in the following examples (replace "/signalr" in the sample code with your desired URL).

Server code that specifies the URL

```
app.MapSignalR("/signalr", new HubConfiguration());
```

JavaScript client code that specifies the URL (with the generated proxy)

```
$.connection.hub.url = "/signalr"
$.connection.hub.start().done(init);
```

JavaScript client code that specifies the URL (without the generated proxy)

```
var connection = $.hubConnection("/signalr", { useDefaultPath: false });
```

.NET client code that specifies the URL

```
var hubConnection = new HubConnection("http://contoso.com/signalr", useDefaultUrl: false);
```

Configuring SignalR Options

Overloads of the `MapSignalR` method enable you to specify a custom URL, a custom dependency resolver, and the following options:

- Enable cross-domain calls using CORS or JSONP from browser clients.

  Typically if the browser loads a page from `http://contoso.com`, the SignalR connection is in the same domain, at `http://contoso.com/signalr`. If the page from `http://contoso.com` makes a connection to `http://fabrikam.com/signalr`, that is a cross-domain connection. For security reasons, cross-domain

connections are disabled by default. For more information, see ASP.NET SignalR Hubs API Guide - JavaScript Client - How to establish a cross-domain connection.

- Enable detailed error messages.

  When errors occur, the default behavior of SignalR is to send to clients a notification message without details about what happened. Sending detailed error information to clients is not recommended in production, because malicious users might be able to use the information in attacks against your application. For troubleshooting, you can use this option to temporarily enable more informative error reporting.

- Disable automatically generated JavaScript proxy files.

  By default, a JavaScript file with proxies for your Hub classes is generated in response to the URL "/signalr/hubs". If you don't want to use the JavaScript proxies, or if you want to generate this file manually and refer to a physical file in your clients, you can use this option to disable proxy generation. For more information, see SignalR Hubs API Guide - JavaScript Client - How to create a physical file for the SignalR generated proxy.

The following example shows how to specify the SignalR connection URL and these options in a call to the `MapSignalR` method. To specify a custom URL, replace "/signalr" in the example with the URL that you want to use.

```
var hubConfiguration = new HubConfiguration();
hubConfiguration.EnableDetailedErrors = true;
hubConfiguration.EnableJavaScriptProxies = false;
app.MapSignalR("/signalr", hubConfiguration);
```

How to create and use Hub classes

To create a Hub, create a class that derives from Microsoft.Aspnet.Signalr.Hub. The following example shows a simple Hub class for a chat application.

```
public class ContosoChatHub : Hub
{
    public async Task NewContosoChatMessage(string name, string message)
    {
        await Clients.All.addNewMessageToPage(name, message);
    }
}
```

In this example, a connected client can call the `NewContosoChatMessage` method, and when it does, the data received is broadcasted to all connected clients.

Hub object lifetime

You don't instantiate the Hub class or call its methods from your own code on the server; all that is done for you by the SignalR Hubs pipeline. SignalR creates a new instance of your Hub class each time it needs to handle a Hub operation such as when a client connects, disconnects, or makes a method call to the server.

Because instances of the Hub class are transient, you can't use them to maintain state from one method call to the next. Each time the server receives a method call from a client, a new instance of your Hub class processes the message. To maintain state through multiple connections and method calls, use some other method such as a database, or a static variable on the Hub class, or a different class that does not derive from `Hub`. If you persist data in memory, using a method such as a static variable on the Hub class, the data will be lost when the app domain recycles.

If you want to send messages to clients from your own code that runs outside the Hub class, you can't do it by

instantiating a Hub class instance, but you can do it by getting a reference to the SignalR context object for your Hub class. For more information, see How to call client methods and manage groups from outside the Hub class later in this topic.

Camel-casing of Hub names in JavaScript clients

By default, JavaScript clients refer to Hubs by using a camel-cased version of the class name. SignalR automatically makes this change so that JavaScript code can conform to JavaScript conventions. The previous example would be referred to as `contosoChatHub` in JavaScript code.

Server

```
public class ContosoChatHub : Hub
```

JavaScript client using generated proxy

```
var contosoChatHubProxy = $.connection.contosoChatHub;
```

If you want to specify a different name for clients to use, add the `HubName` attribute. When you use a `HubName` attribute, there is no name change to camel case on JavaScript clients.

Server

```
[HubName("PascalCaseContosoChatHub")]
public class ContosoChatHub : Hub
```

JavaScript client using generated proxy

```
var contosoChatHubProxy = $.connection.PascalCaseContosoChatHub;
```

Multiple Hubs

You can define multiple Hub classes in an application. When you do that, the connection is shared but groups are separate:

- All clients will use the same URL to establish a SignalR connection with your service ("/signalr" or your custom URL if you specified one), and that connection is used for all Hubs defined by the service.

  There is no performance difference for multiple Hubs compared to defining all Hub functionality in a single class.

- All Hubs get the same HTTP request information.

  Since all Hubs share the same connection, the only HTTP request information that the server gets is what comes in the original HTTP request that establishes the SignalR connection. If you use the connection request to pass information from the client to the server by specifying a query string, you can't provide different query strings to different Hubs. All Hubs will receive the same information.

- The generated JavaScript proxies file will contain proxies for all Hubs in one file.

  For information about JavaScript proxies, see SignalR Hubs API Guide - JavaScript Client - The generated proxy and what it does for you.

- Groups are defined within Hubs.

  In SignalR you can define named groups to broadcast to subsets of connected clients. Groups are maintained separately for each Hub. For example, a group named "Administrators" would include one set

of clients for your `ContosoChatHub` class, and the same group name would refer to a different set of clients for your `StockTickerHub` class.

Strongly-Typed Hubs

To define an interface for your hub methods that your client can reference (and enable Intellisense on your hub methods), derive your hub from `Hub<T>` (introduced in SignalR 2.1) rather than `Hub`:

```
public class StrongHub : Hub<IClient>
{
    public async Task Send(string message)
    {
        await Clients.All.NewMessage(message);
    }
}

public interface IClient
{
    Task NewMessage(string message);
}
```

How to define methods in the Hub class that clients can call

To expose a method on the Hub that you want to be callable from the client, declare a public method, as shown in the following examples.

```
public class ContosoChatHub : Hub
{
    public async Task NewContosoChatMessage(string name, string message)
    {
        await Clients.All.addNewMessageToPage(name, message);
    }
}
```

```
public class StockTickerHub : Hub
{
    public IEnumerable<Stock> GetAllStocks()
    {
        return _stockTicker.GetAllStocks();
    }
}
```

You can specify a return type and parameters, including complex types and arrays, as you would in any C# method. Any data that you receive in parameters or return to the caller is communicated between the client and the server by using JSON, and SignalR handles the binding of complex objects and arrays of objects automatically.

Camel-casing of method names in JavaScript clients

By default, JavaScript clients refer to Hub methods by using a camel-cased version of the method name. SignalR automatically makes this change so that JavaScript code can conform to JavaScript conventions.

Server

```
public void NewContosoChatMessage(string userName, string message)
```

JavaScript client using generated proxy

```
contosoChatHubProxy.server.newContosoChatMessage(userName, message);
```

If you want to specify a different name for clients to use, add the `HubMethodName` attribute.

Server

```
[HubMethodName("PascalCaseNewContosoChatMessage")]
public void NewContosoChatMessage(string userName, string message)
```

JavaScript client using generated proxy

```
contosoChatHubProxy.server.PascalCaseNewContosoChatMessage(userName, message);
```

When to execute asynchronously

If the method will be long-running or has to do work that would involve waiting, such as a database lookup or a web service call, make the Hub method asynchronous by returning a Task (in place of `void` return) or Task<T> object (in place of `T` return type). When you return a `Task` object from the method, SignalR waits for the `Task` to complete, and then it sends the unwrapped result back to the client, so there is no difference in how you code the method call in the client.

Making a Hub method asynchronous avoids blocking the connection when it uses the WebSocket transport. When a Hub method executes synchronously and the transport is WebSocket, subsequent invocations of methods on the Hub from the same client are blocked until the Hub method completes.

The following example shows the same method coded to run synchronously or asynchronously, followed by JavaScript client code that works for calling either version.

Synchronous

```
public IEnumerable<Stock> GetAllStocks()
{
    // Returns data from memory.
    return _stockTicker.GetAllStocks();
}
```

Asynchronous

```
public async Task<IEnumerable<Stock>> GetAllStocks()
{
    // Returns data from a web service.
    var uri = Util.getServiceUri("Stocks");
    using (HttpClient httpClient = new HttpClient())
    {
        var response = await httpClient.GetAsync(uri);
        return (await response.Content.ReadAsAsync<IEnumerable<Stock>>());
    }
}
```

JavaScript client using generated proxy

```
stockTickerHubProxy.server.getAllStocks().done(function (stocks) {
    $.each(stocks, function () {
        alert(this.Symbol + ' ' + this.Price);
    });
});
```

For more information about how to use asynchronous methods in ASP.NET 4.5, see Using Asynchronous Methods in ASP.NET MVC 4.

Defining Overloads

If you want to define overloads for a method, the number of parameters in each overload must be different. If you differentiate an overload just by specifying different parameter types, your Hub class will compile but the SignalR service will throw an exception at run time when clients try to call one of the overloads.

Reporting progress from hub method invocations

SignalR 2.1 adds support for the progress reporting pattern introduced in .NET 4.5. To implement progress reporting, define an `IProgress<T>` parameter for your hub method that your client can access:

```
public class ProgressHub : Hub
{
    public async Task<string> DoLongRunningThing(IProgress<int> progress)
    {
        for (int i = 0; i <= 100; i+=5)
        {
            await Task.Delay(200);
            progress.Report(i);
        }
        return "Job complete!";
    }
}
```

When writing a long-running server method, it is important to use an asynchronous programming pattern like Async/ Await rather than blocking the hub thread.

How to call client methods from the Hub class

To call client methods from the server, use the `Clients` property in a method in your Hub class. The following example shows server code that calls `addNewMessageToPage` on all connected clients, and client code that defines the method in a JavaScript client.

Server

```
public class ContosoChatHub : Hub
{
    public async Task NewContosoChatMessage(string name, string message)
    {
        await Clients.All.addNewMessageToPage(name, message);
    }
}
```

Invoking a client method is an asynchronous operation and returns a `Task`. Use `await`:

- To ensure the message is sent without error.
- To enable catching and handling errors in a try-catch block.

JavaScript client using generated proxy

```
contosoChatHubProxy.client.addNewMessageToPage = function (name, message) {
    // Add the message to the page.
    $('#discussion').append('<li><strong>' + htmlEncode(name)
        + '</strong>: ' + htmlEncode(message) + '<li>');
};
```

You can't get a return value from a client method; syntax such as `int x = Clients.All.add(1,1)` does not work.

You can specify complex types and arrays for the parameters. The following example passes a complex type to the client in a method parameter.

Server code that calls a client method using a complex object

```
public async Task SendMessage(string name, string message)
{
    await Clients.All.addContosoChatMessageToPage(new ContosoChatMessage() { UserName = name, Message =
message });
}
```

Server code that defines the complex object

```
public class ContosoChatMessage
{
    public string UserName { get; set; }
    public string Message { get; set; }
}
```

JavaScript client using generated proxy

```
var contosoChatHubProxy = $.connection.contosoChatHub;
contosoChatHubProxy.client.addMessageToPage = function (message) {
    console.log(message.UserName + ' ' + message.Message);
});
```

Selecting which clients will receive the RPC

The Clients property returns a HubConnectionContext object that provides several options for specifying which clients will receive the RPC:

- All connected clients.

  ```
  Clients.All.addContosoChatMessageToPage(name, message);
  ```

- Only the calling client.

  ```
  Clients.Caller.addContosoChatMessageToPage(name, message);
  ```

- All clients except the calling client.

  ```
  Clients.Others.addContosoChatMessageToPage(name, message);
  ```

- A specific client identified by connection ID.

```
Clients.Client(Context.ConnectionId).addContosoChatMessageToPage(name, message);
```

This example calls `addContosoChatMessageToPage` on the calling client and has the same effect as using `Clients.Caller`.

- All connected clients except the specified clients, identified by connection ID.

```
Clients.AllExcept(connectionId1, connectionId2).addContosoChatMessageToPage(name, message);
```

- All connected clients in a specified group.

```
Clients.Group(groupName).addContosoChatMessageToPage(name, message);
```

- All connected clients in a specified group except the specified clients, identified by connection ID.

```
Clients.Group(groupName, connectionId1, connectionId2).addContosoChatMessageToPage(name, message);
```

- All connected clients in a specified group except the calling client.

```
Clients.OthersInGroup(groupName).addContosoChatMessageToPage(name, message);
```

- A specific user, identified by userId.

```
Clients.User(userid).addContosoChatMessageToPage(name, message);
```

By default, this is `IPrincipal.Identity.Name`, but this can be changed by registering an implementation of IUserIdProvider with the global host.

- All clients and groups in a list of connection IDs.

```
Clients.Clients(ConnectionIds).broadcastMessage(name, message);
```

- A list of groups.

```
Clients.Groups(GroupIds).broadcastMessage(name, message);
```

- A user by name.

```
Clients.Client(username).broadcastMessage(name, message);
```

- A list of user names (introduced in SignalR 2.1).

```
Clients.Users(new string[] { "myUser", "myUser2" }).broadcastMessage(name, message);
```

No compile-time validation for method names

The method name that you specify is interpreted as a dynamic object, which means there is no IntelliSense or compile-time validation for it. The expression is evaluated at run time. When the method call executes, SignalR sends the method name and the parameter values to the client, and if the client has a method that matches the

name, that method is called and the parameter values are passed to it. If no matching method is found on the client, no error is raised. For information about the format of the data that SignalR transmits to the client behind the scenes when you call a client method, see Introduction to SignalR.

Case-insensitive method name matching

Method name matching is case-insensitive. For example, `Clients.All.addContosoChatMessageToPage` on the server will execute `AddContosoChatMessageToPage`, `addcontosochatmessagetopage`, or `addContosoChatMessageToPage` on the client.

Asynchronous execution

The method that you call executes asynchronously. Any code that comes after a method call to a client will execute immediately without waiting for SignalR to finish transmitting data to clients unless you specify that the subsequent lines of code should wait for method completion. The following code example shows how to execute two client methods sequentially.

Using Await (.NET 4.5)

```
public async Task NewContosoChatMessage(string name, string message)
{
    await Clients.Others.addContosoChatMessageToPage(data);
    await Clients.Caller.notifyMessageSent();
}
```

If you use `await` to wait until a client method finishes before the next line of code executes, that does not mean that clients will actually receive the message before the next line of code executes. "Completion" of a client method call only means that SignalR has done everything necessary to send the message. If you need verification that clients received the message, you have to program that mechanism yourself. For example, you could code a `MessageReceived` method on the Hub, and in the `addContosoChatMessageToPage` method on the client you could call `MessageReceived` after you do whatever work you need to do on the client. In `MessageReceived` in the Hub you can do whatever work depends on actual client reception and processing of the original method call.

How to use a string variable as the method name

If you want to invoke a client method by using a string variable as the method name, cast `Clients.All` (or `Clients.Others`, `Clients.Caller`, etc.) to `IClientProxy` and then call Invoke(methodName, args...).

```
public async Task NewContosoChatMessage(string name, string message)
{
    string methodToCall = "addContosoChatMessageToPage";
    IClientProxy proxy = Clients.All;
    await proxy.Invoke(methodToCall, name, message);
}
```

How to manage group membership from the Hub class

Groups in SignalR provide a method for broadcasting messages to specified subsets of connected clients. A group can have any number of clients, and a client can be a member of any number of groups.

To manage group membership, use the Add and Remove methods provided by the `Groups` property of the Hub class. The following example shows the `Groups.Add` and `Groups.Remove` methods used in Hub methods that are called by client code, followed by JavaScript client code that calls them.

Server

```
public class ContosoChatHub : Hub
{
    public Task JoinGroup(string groupName)
    {
        return Groups.Add(Context.ConnectionId, groupName);
    }

    public Task LeaveGroup(string groupName)
    {
        return Groups.Remove(Context.ConnectionId, groupName);
    }
}
```

JavaScript client using generated proxy

```
contosoChatHubProxy.server.joinGroup(groupName);
```

```
contosoChatHubProxy.server.leaveGroup(groupName);
```

You don't have to explicitly create groups. In effect a group is automatically created the first time you specify its name in a call to `Groups.Add`, and it is deleted when you remove the last connection from membership in it.

There is no API for getting a group membership list or a list of groups. SignalR sends messages to clients and groups based on a pub/sub model, and the server does not maintain lists of groups or group memberships. This helps maximize scalability, because whenever you add a node to a web farm, any state that SignalR maintains has to be propagated to the new node.

Asynchronous execution of Add and Remove methods

The `Groups.Add` and `Groups.Remove` methods execute asynchronously. If you want to add a client to a group and immediately send a message to the client by using the group, you have to make sure that the `Groups.Add` method finishes first. The following code example shows how to do that.

Adding a client to a group and then messaging that client

```
public async Task JoinGroup(string groupName)
{
    await Groups.Add(Context.ConnectionId, groupName);
    await Clients.Group(groupname).addContosoChatMessageToPage(Context.ConnectionId + " added to group");
}
```

Group membership persistence

SignalR tracks connections, not users, so if you want a user to be in the same group every time the user establishes a connection, you have to call `Groups.Add` every time the user establishes a new connection.

After a temporary loss of connectivity, sometimes SignalR can restore the connection automatically. In that case, SignalR is restoring the same connection, not establishing a new connection, and so the client's group membership is automatically restored. This is possible even when the temporary break is the result of a server reboot or failure, because connection state for each client, including group memberships, is round-tripped to the client. If a server goes down and is replaced by a new server before the connection times out, a client can reconnect automatically to the new server and re-enroll in groups it is a member of.

When a connection can't be restored automatically after a loss of connectivity, or when the connection times out, or when the client disconnects (for example, when a browser navigates to a new page), group memberships are lost. The next time the user connects will be a new connection. To maintain group memberships when the same user establishes a new connection, your application has to track the associations between users and groups, and

restore group memberships each time a user establishes a new connection.

For more information about connections and reconnections, see How to handle connection lifetime events in the Hub class later in this topic.

Single-user groups

Applications that use SignalR typically have to keep track of the associations between users and connections in order to know which user has sent a message and which user(s) should be receiving a message. Groups are used in one of the two commonly used patterns for doing that.

- Single-user groups.

  You can specify the user name as the group name, and add the current connection ID to the group every time the user connects or reconnects. To send messages to the user you send to the group. A disadvantage of this method is that the group doesn't provide you with a way to find out if the user is online or offline.

- Track associations between user names and connection IDs.

  You can store an association between each user name and one or more connection IDs in a dictionary or database, and update the stored data each time the user connects or disconnects. To send messages to the user you specify the connection IDs. A disadvantage of this method is that it takes more memory.

How to handle connection lifetime events in the Hub class

Typical reasons for handling connection lifetime events are to keep track of whether a user is connected or not, and to keep track of the association between user names and connection IDs. To run your own code when clients connect or disconnect, override the `OnConnected`, `OnDisconnected`, and `OnReconnected` virtual methods of the Hub class, as shown in the following example.

```
public class ContosoChatHub : Hub
{
    public override Task OnConnected()
    {
        // Add your own code here.
        // For example: in a chat application, record the association between
        // the current connection ID and user name, and mark the user as online.
        // After the code in this method completes, the client is informed that
        // the connection is established; for example, in a JavaScript client,
        // the start().done callback is executed.
        return base.OnConnected();
    }

    public override Task OnDisconnected(bool stopCalled)
    {
        // Add your own code here.
        // For example: in a chat application, mark the user as offline,
        // delete the association between the current connection id and user name.
        return base.OnDisconnected(stopCalled);
    }

    public override Task OnReconnected()
    {
        // Add your own code here.
        // For example: in a chat application, you might have marked the
        // user as offline after a period of inactivity; in that case
        // mark the user as online again.
        return base.OnReconnected();
    }
}
```

When OnConnected, OnDisconnected, and OnReconnected are called

Each time a browser navigates to a new page, a new connection has to be established, which means SignalR will execute the `OnDisconnected` method followed by the `OnConnected` method. SignalR always creates a new connection ID when a new connection is established.

The `OnReconnected` method is called when there has been a temporary break in connectivity that SignalR can automatically recover from, such as when a cable is temporarily disconnected and reconnected before the connection times out. The `OnDisconnected` method is called when the client is disconnected and SignalR can't automatically reconnect, such as when a browser navigates to a new page. Therefore, a possible sequence of events for a given client is `OnConnected`, `OnReconnected`, `OnDisconnected`; or `OnConnected`, `OnDisconnected`. You won't see the sequence `OnConnected`, `OnDisconnected`, `OnReconnected` for a given connection.

The `OnDisconnected` method doesn't get called in some scenarios, such as when a server goes down or the App Domain gets recycled. When another server comes on line or the App Domain completes its recycle, some clients may be able to reconnect and fire the `OnReconnected` event.

For more information, see Understanding and Handling Connection Lifetime Events in SignalR.

Caller state not populated

The connection lifetime event handler methods are called from the server, which means that any state that you put in the `state` object on the client will not be populated in the `Caller` property on the server. For information about the `state` object and the `Caller` property, see How to pass state between clients and the Hub class later in this topic.

How to get information about the client from the Context property

To get information about the client, use the `Context` property of the Hub class. The `Context` property returns a HubCallerContext object which provides access to the following information:

- The connection ID of the calling client.

  ```
  string connectionID = Context.ConnectionId;
  ```

  The connection ID is a GUID that is assigned by SignalR (you can't specify the value in your own code). There is one connection ID for each connection, and the same connection ID is used by all Hubs if you have multiple Hubs in your application.

- HTTP header data.

  ```
  System.Collections.Specialized.NameValueCollection headers = Context.Request.Headers;
  ```

  You can also get HTTP headers from `Context.Headers`. The reason for multiple references to the same thing is that `Context.Headers` was created first, the `Context.Request` property was added later, and `Context.Headers` was retained for backward compatibility.

- Query string data.

  ```
  System.Collections.Specialized.NameValueCollection queryString = Context.Request.QueryString;
  string parameterValue = queryString["parametername"]
  ```

  You can also get query string data from `Context.QueryString`.

  The query string that you get in this property is the one that was used with the HTTP request that established the SignalR connection. You can add query string parameters in the client by configuring the connection, which is a convenient way to pass data about the client from the client to the server. The

following example shows one way to add a query string in a JavaScript client when you use the generated proxy.

```
$.connection.hub.qs = { "version" : "1.0" };
```

For more information about setting query string parameters, see the API guides for the JavaScript and .NET clients.

You can find the transport method used for the connection in the query string data, along with some other values used internally by SignalR:

```
string transportMethod = queryString["transport"];
```

The value of `transportMethod` will be "webSockets", "serverSentEvents", "foreverFrame" or "longPolling". Note that if you check this value in the `OnConnected` event handler method, in some scenarios you might initially get a transport value that is not the final negotiated transport method for the connection. In that case the method will throw an exception and will be called again later when the final transport method is established.

- Cookies.

```
System.Collections.Generic.IDictionary<string, Cookie> cookies = Context.Request.Cookies;
```

You can also get cookies from `Context.RequestCookies`.

- User information.

```
System.Security.Principal.IPrincipal user = Context.User;
```

- The HttpContext object for the request :

```
System.Web.HttpContextBase httpContext = Context.Request.GetHttpContext();
```

Use this method instead of getting `HttpContext.Current` to get the `HttpContext` object for the SignalR connection.

How to pass state between clients and the Hub class

The client proxy provides a `state` object in which you can store data that you want to be transmitted to the server with each method call. On the server you can access this data in the `Clients.Caller` property in Hub methods that are called by clients. The `Clients.Caller` property is not populated for the connection lifetime event handler methods `OnConnected`, `OnDisconnected`, and `OnReconnected`.

Creating or updating data in the `state` object and the `Clients.Caller` property works in both directions. You can update values in the server and they are passed back to the client.

The following example shows JavaScript client code that stores state for transmission to the server with every method call.

```
contosoChatHubProxy.state.userName = "Fadi Fakhouri";
contosoChatHubProxy.state.computerName = "fadivm1";
```

The following example shows the equivalent code in a .NET client.

```
contosoChatHubProxy["userName"] = "Fadi Fakhouri";
chatHubProxy["computerName"] = "fadivm1";
```

In your Hub class, you can access this data in the `Clients.Caller` property. The following example shows code that retrieves the state referred to in the previous example.

```
public async Task NewContosoChatMessage(string data)
{
    string userName = Clients.Caller.userName;
    string computerName = Clients.Caller.computerName;
    await Clients.Others.addContosoChatMessageToPage(message, userName, computerName);
}
```

> **NOTE**
> This mechanism for persisting state is not intended for large amounts of data, since everything you put in the `state` or `Clients.Caller` property is round-tripped with every method invocation. It's useful for smaller items such as user names or counters.

In VB.NET or in a strongly-typed hub, the caller state object can't be accessed through `Clients.Caller`; instead, use `Clients.CallerState` (introduced in SignalR 2.1):

Using CallerState in C#

```
public async Task NewContosoChatMessage(string data)
{
    string userName = Clients.CallerState.userName;
    string computerName = Clients.CallerState.computerName;
    await Clients.Others.addContosoChatMessageToPage(data, userName, computerName);
}
```

Using CallerState in Visual Basic

```
Public Async Function NewContosoChatMessage(message As String) As Task
    Dim userName As String = Clients.CallerState.userName
    Dim computerName As String = Clients.CallerState.computerName
    Await Clients.Others.addContosoChatMessageToPage(message, userName, computerName)
End Sub
```

How to handle errors in the Hub class

To handle errors that occur in your Hub class methods, first ensure you "observe" any exceptions from async operations (such as invoking client methods) by using `await`. Then use one or more of the following methods:

- Wrap your method code in try-catch blocks and log the exception object. For debugging purposes you can send the exception to the client, but for security reasons sending detailed information to clients in production is not recommended.
- Create a Hubs pipeline module that handles the OnIncomingError method. The following example shows a pipeline module that logs errors, followed by code in Startup.cs that injects the module into the Hubs pipeline.

```
public class ErrorHandlingPipelineModule : HubPipelineModule
{
    protected override void OnIncomingError(ExceptionContext exceptionContext,
IHubIncomingInvokerContext invokerContext)
    {
        Debug.WriteLine("=> Exception " + exceptionContext.Error.Message);
        if (exceptionContext.Error.InnerException != null)
        {
            Debug.WriteLine("=> Inner Exception " + exceptionContext.Error.InnerException.Message);
        }
        base.OnIncomingError(exceptionContext, invokerContext);

    }
}
```

```
public void Configuration(IAppBuilder app)
{
    // Any connection or hub wire up and configuration should go here
    GlobalHost.HubPipeline.AddModule(new ErrorHandlingPipelineModule());
    app.MapSignalR();
}
```

- Use the `HubException` class (introduced in SignalR 2). This error can be thrown from any hub invocation. The `HubError` constructor takes a string message, and an object for storing extra error data. SignalR will auto-serialize the exception and send it to the client, where it will be used to reject or fail the hub method invocation.

  The following code samples demonstrate how to throw a `HubException` during a Hub invocation, and how to handle the exception on JavaScript and .NET clients.

  #### Server code demonstrating the HubException class

```
public class MyHub : Hub
{
    public async Task Send(string message)
    {
        if(message.Contains("<script>"))
        {
            throw new HubException("This message will flow to the client", new { user =
Context.User.Identity.Name, message = message });
        }

        await Clients.All.send(message);
    }
}
```

  #### JavaScript client code demonstrating response to throwing a HubException in a hub

```
myHub.server.send("<script>")
            .fail(function (e) {
                if (e.source === 'HubException') {
                    console.log(e.message + ' : ' + e.data.user);
                }
            });
```

  #### .NET client code demonstrating response to throwing a HubException in a hub

```
try
{
    await myHub.Invoke("Send", "<script>");
}
catch(HubException ex)
{
    Console.WriteLine(ex.Message);
}
```

For more information about Hub pipeline modules, see How to customize the Hubs pipeline later in this topic.

How to enable tracing

To enable server-side tracing, add a system.diagnostics element to your Web.config file, as shown in this example:

```
<configuration>
  <configSections>
    <!-- For more information on Entity Framework configuration, visit https://go.microsoft.com/fwlink/?
LinkID=237468 -->
    <section name="entityFramework" type="System.Data.Entity.Internal.ConfigFile.EntityFrameworkSection,
EntityFramework, Version=5.0.0.0, Culture=neutral, PublicKeyToken=b77a5c561934e089" requirePermission="false"
/>
  </configSections>
  <connectionStrings>
    <add name="SignalRSamples" connectionString="Data Source=(local);Initial
Catalog=SignalRSamples;Integrated Security=SSPI;Asynchronous Processing=True;" />
    <add name="SignalRSamplesWithMARS" connectionString="Data Source=(local);Initial
Catalog=SignalRSamples;Integrated Security=SSPI;Asynchronous Processing=True;MultipleActiveResultSets=true;"
/>
  </connectionStrings>
  <system.web>
    <compilation debug="true" targetFramework="4.5" />
    <httpRuntime targetFramework="4.5" />
  </system.web>
  <system.webServer>
    <modules runAllManagedModulesForAllRequests="true" />
  </system.webServer>
  <system.diagnostics>
    <sources>
      <source name="SignalR.SqlMessageBus">
        <listeners>
          <add name="SignalR-Bus" />
        </listeners>
      </source>
     <source name="SignalR.ServiceBusMessageBus">
        <listeners>
            <add name="SignalR-Bus" />
        </listeners>
     </source>
     <source name="SignalR.ScaleoutMessageBus">
        <listeners>
            <add name="SignalR-Bus" />
        </listeners>
      </source>
      <source name="SignalR.Transports.WebSocketTransport">
        <listeners>
          <add name="SignalR-Transports" />
        </listeners>
      </source>
      <source name="SignalR.Transports.ServerSentEventsTransport">
          <listeners>
              <add name="SignalR-Transports" />
          </listeners>
      </source>
      <source name="SignalR.Transports.ForeverFrameTransport">
```

```
          <listeners>
              <add name="SignalR-Transports" />
          </listeners>
      </source>
      <source name="SignalR.Transports.LongPollingTransport">
        <listeners>
            <add name="SignalR-Transports" />
        </listeners>
      </source>
      <source name="SignalR.Transports.TransportHeartBeat">
        <listeners>
            <add name="SignalR-Transports" />
        </listeners>
      </source>
    </sources>
    <switches>
      <add name="SignalRSwitch" value="Verbose" />
    </switches>
    <sharedListeners>
      <add name="SignalR-Transports"
           type="System.Diagnostics.TextWriterTraceListener"
           initializeData="transports.log.txt" />
        <add name="SignalR-Bus"
           type="System.Diagnostics.TextWriterTraceListener"
           initializeData="bus.log.txt" />
    </sharedListeners>
    <trace autoflush="true" />
  </system.diagnostics>
  <entityFramework>
    <defaultConnectionFactory type="System.Data.Entity.Infrastructure.LocalDbConnectionFactory,
EntityFramework">
      <parameters>
        <parameter value="v11.0" />
      </parameters>
    </defaultConnectionFactory>
  </entityFramework>
</configuration>
```

When you run the application in Visual Studio, you can view the logs in the **Output** window.

How to call client methods and manage groups from outside the Hub class

To call client methods from a different class than your Hub class, get a reference to the SignalR context object for the Hub and use that to call methods on the client or manage groups.

The following sample `StockTicker` class gets the context object, stores it in an instance of the class, stores the class instance in a static property, and uses the context from the singleton class instance to call the `updateStockPrice` method on clients that are connected to a Hub named `StockTickerHub`.

```
// For the complete example, go to
// http://www.asp.net/signalr/overview/getting-started/tutorial-server-broadcast-with-aspnet-signalr
// This sample only shows code related to getting and using the SignalR context.
public class StockTicker
{
    // Singleton instance
    private readonly static Lazy<StockTicker> _instance = new Lazy<StockTicker>(
        () => new StockTicker(GlobalHost.ConnectionManager.GetHubContext<StockTickerHub>()));

    private IHubContext _context;

    private StockTicker(IHubContext context)
    {
        _context = context;
    }

    // This method is invoked by a Timer object.
    private void UpdateStockPrices(object state)
    {
        foreach (var stock in _stocks.Values)
        {
            if (TryUpdateStockPrice(stock))
            {
                _context.Clients.All.updateStockPrice(stock);
            }
        }
    }
```

If you need to use the context multiple-times in a long-lived object, get the reference once and save it rather than getting it again each time. Getting the context once ensures that SignalR sends messages to clients in the same sequence in which your Hub methods make client method invocations. For a tutorial that shows how to use the SignalR context for a Hub, see Server Broadcast with ASP.NET SignalR.

Calling client methods

You can specify which clients will receive the RPC, but you have fewer options than when you call from a Hub class. The reason for this is that the context is not associated with a particular call from a client, so any methods that require knowledge of the current connection ID, such as `Clients.Others`, or `Clients.Caller`, or `Clients.OthersInGroup`, are not available. The following options are available:

- All connected clients.

  ```
  context.Clients.All.addContosoChatMessageToPage(name, message);
  ```

- A specific client identified by connection ID.

  ```
  context.Clients.Client(connectionID).addContosoChatMessageToPage(name, message);
  ```

- All connected clients except the specified clients, identified by connection ID.

  ```
  context.Clients.AllExcept(connectionId1, connectionId2).addContosoChatMessageToPage(name, message);
  ```

- All connected clients in a specified group.

  ```
  context.Clients.Group(groupName).addContosoChatMessageToPage(name, message);
  ```

- All connected clients in a specified group except specified clients, identified by connection ID.

```
Clients.Group(groupName, connectionId1, connectionId2).addContosoChatMessageToPage(name, message);
```

If you are calling into your non-Hub class from methods in your Hub class, you can pass in the current connection ID and use that with `Clients.Client`, `Clients.AllExcept`, or `Clients.Group` to simulate `Clients.Caller`, `Clients.Others`, or `Clients.OthersInGroup`. In the following example, the `MoveShapeHub` class passes the connection ID to the `Broadcaster` class so that the `Broadcaster` class can simulate `Clients.Others`.

```
// For the complete example, see
// http://www.asp.net/signalr/overview/signalr-20/getting-started-with-signalr-20/tutorial-server-broadcast-
with-signalr-20
// This sample only shows code that passes connection ID to the non-Hub class,
// in order to simulate Clients.Others.
public class MoveShapeHub : Hub
{
    // Code not shown puts a singleton instance of Broadcaster in this variable.
    private Broadcaster _broadcaster;

    public void UpdateModel(ShapeModel clientModel)
    {
        clientModel.LastUpdatedBy = Context.ConnectionId;
        // Update the shape model within our broadcaster
        _broadcaster.UpdateShape(clientModel);
    }
}

public class Broadcaster
{
    public Broadcaster()
    {
        _hubContext = GlobalHost.ConnectionManager.GetHubContext<MoveShapeHub>();
    }

    public void UpdateShape(ShapeModel clientModel)
    {
        _model = clientModel;
        _modelUpdated = true;
    }

    // Called by a Timer object.
    public void BroadcastShape(object state)
    {
        if (_modelUpdated)
        {
            _hubContext.Clients.AllExcept(_model.LastUpdatedBy).updateShape(_model);
            _modelUpdated = false;
        }
    }
}
```

Managing group membership

For managing groups you have the same options as you do in a Hub class.

- Add a client to a group

```
context.Groups.Add(connectionID, groupName);
```

- Remove a client from a group

```
context.Groups.Remove(connectionID, groupName);
```

How to customize the Hubs pipeline

SignalR enables you to inject your own code into the Hub pipeline. The following example shows a custom Hub pipeline module that logs each incoming method call received from the client and outgoing method call invoked on the client:

```
public class LoggingPipelineModule : HubPipelineModule
{
    protected override bool OnBeforeIncoming(IHubIncomingInvokerContext context)
    {
        Debug.WriteLine("=> Invoking " + context.MethodDescriptor.Name + " on hub " +
context.MethodDescriptor.Hub.Name);
        return base.OnBeforeIncoming(context);
    }
    protected override bool OnBeforeOutgoing(IHubOutgoingInvokerContext context)
    {
        Debug.WriteLine("<= Invoking " + context.Invocation.Method + " on client hub " +
context.Invocation.Hub);
        return base.OnBeforeOutgoing(context);
    }
}
```

The following code in the *Startup.cs* file registers the module to run in the Hub pipeline:

```
public void Configuration(IAppBuilder app)
{
    GlobalHost.HubPipeline.AddModule(new LoggingPipelineModule());
    app.MapSignalR();
}
```

There are many different methods that you can override. For a complete list, see HubPipelineModule Methods.

ASP.NET SignalR Hubs API Guide - JavaScript Client

2/20/2020 • 22 minutes to read • Edit Online

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This document provides an introduction to using the Hubs API for SignalR version 2 in JavaScript clients, such as browsers and Windows Store (WinJS) applications.

The SignalR Hubs API enables you to make remote procedure calls (RPCs) from a server to connected clients and from clients to the server. In server code, you define methods that can be called by clients, and you call methods that run on the client. In client code, you define methods that can be called from the server, and you call methods that run on the server. SignalR takes care of all of the client-to-server plumbing for you.

SignalR also offers a lower-level API called Persistent Connections. For an introduction to SignalR, Hubs, and Persistent Connections, see Introduction to SignalR.

Software versions used in this topic

- Visual Studio 2017
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Overview

This document contains the following sections:

- The generated proxy and what it does for you
  - When to use the generated proxy
- Client Setup
  - How to reference the dynamically generated proxy
  - How to create a physical file for the SignalR generated proxy
- How to establish a connection
  - $.connection.hub is the same object that $.hubConnection() creates
  - Asynchronous execution of the start method
- How to establish a cross-domain connection

- How to configure the connection
  - How to specify query string parameters
  - How to specify the transport method
- How to get a proxy for a Hub class
- How to define methods on the client that the server can call
- How to call server methods from the client
- How to handle connection lifetime events
- How to handle errors
- How to enable client-side logging

For documentation on how to program the server or .NET clients, see the following resources:

- SignalR Hubs API Guide - Server
- SignalR Hubs API Guide - .NET Client

The SignalR 2 server component is only available on .NET 4.5 (though there is a .NET client for SignalR 2 on .NET 4.0).

The generated proxy and what it does for you

You can program a JavaScript client to communicate with a SignalR service with or without a proxy that SignalR generates for you. What the proxy does for you is simplify the syntax of the code you use to connect, write methods that the server calls, and call methods on the server.

When you write code to call server methods, the generated proxy enables you to use syntax that looks as though you were executing a local function: you can write `serverMethod(arg1, arg2)` instead of `invoke('serverMethod', arg1, arg2)`. The generated proxy syntax also enables an immediate and intelligible client-side error if you mistype a server method name. And if you manually create the file that defines the proxies, you can also get IntelliSense support for writing code that calls server methods.

For example, suppose you have the following Hub class on the server:

```
public class ContosoChatHub : Hub
{
    public void NewContosoChatMessage(string name, string message)
    {
        Clients.All.addContosoChatMessageToPage(name, message);
    }
}
```

The following code examples show what JavaScript code looks like for invoking the `NewContosoChatMessage` method on the server and receiving invocations of the `addContosoChatMessageToPage` method from the server.

With the generated proxy

```
var contosoChatHubProxy = $.connection.contosoChatHub;
contosoChatHubProxy.client.addContosoChatMessageToPage = function (name, message) {
    console.log(name + ' ' + message);
};
$.connection.hub.start().done(function () {
    // Wire up Send button to call NewContosoChatMessage on the server.
    $('#newContosoChatMessage').click(function () {
         contosoChatHubProxy.server.newContosoChatMessage($('#displayname').val(), $('#message').val());
         $('#message').val('').focus();
     });
});
```

Without the generated proxy

```
var connection = $.hubConnection();
var contosoChatHubProxy = connection.createHubProxy('contosoChatHub');
contosoChatHubProxy.on('addContosoChatMessageToPage', function(name, message) {
    console.log(name + ' ' + message);
});
connection.start().done(function() {
    // Wire up Send button to call NewContosoChatMessage on the server.
    $('#newContosoChatMessage').click(function () {
        contosoChatHubProxy.invoke('newContosoChatMessage', $('#displayname').val(), $('#message').val());
        $('#message').val('').focus();
                });
    });
```

When to use the generated proxy

If you want to register multiple event handlers for a client method that the server calls, you can't use the generated proxy. Otherwise, you can choose to use the generated proxy or not based on your coding preference. If you choose not to use it, you don't have to reference the "signalr/hubs" URL in a `script` element in your client code.

Client setup

A JavaScript client requires references to jQuery and the SignalR core JavaScript file. The jQuery version must be 1.6.4 or major later versions, such as 1.7.2, 1.8.2, or 1.9.1. If you decide to use the generated proxy, you also need a reference to the SignalR generated proxy JavaScript file. The following example shows what the references might look like in an HTML page that uses the generated proxy.

```
<script src="Scripts/jquery-1.10.2.min.js"></script>
<script src="Scripts/jquery.signalR-2.1.0.min.js"></script>
<script src="signalr/hubs"></script>
```

These references must be included in this order: jQuery first, SignalR core after that, and SignalR proxies last.

How to reference the dynamically generated proxy

In the preceding example, the reference to the SignalR generated proxy is to dynamically generated JavaScript code, not to a physical file. SignalR creates the JavaScript code for the proxy on the fly and serves it to the client in response to the "/signalr/hubs" URL. If you specified a different base URL for SignalR connections on the server in your `MapSignalR` method, the URL for the dynamically generated proxy file is your custom URL with "/hubs" appended to it.

> **NOTE**
> For Windows 8 (Windows Store) JavaScript clients, use the physical proxy file instead of the dynamically generated one. For more information, see How to create a physical file for the SignalR generated proxy later in this topic.

In an ASP.NET MVC 4 or 5 Razor view, use the tilde to refer to the application root in your proxy file reference:

```
<script src="~/signalr/hubs"></script>
```

For more information about using SignalR in MVC 5, see Getting Started with SignalR and MVC 5.

In an ASP.NET MVC 3 Razor view, use `Url.Content` for your proxy file reference:

```
<script src="@Url.Content("~/signalr/hubs")"></script>
```

In an ASP.NET Web Forms application, use `ResolveClientUrl` for your proxies file reference or register it via the ScriptManager using an app root relative path (starting with a tilde):

```
<script src='<%: ResolveClientUrl("~/signalr/hubs") %>'></script>
```

As a general rule, use the same method for specifying the "/signalr/hubs" URL that you use for CSS or JavaScript files. If you specify a URL without using a tilde, in some scenarios your application will work correctly when you test in Visual Studio using IIS Express but will fail with a 404 error when you deploy to full IIS. For more information, see **Resolving References to Root-Level Resources** in Web Servers in Visual Studio for ASP.NET Web Projects on the MSDN site.

When you run a web project in Visual Studio 2017 in debug mode, and if you use Internet Explorer as your browser, you can see the proxy file in **Solution Explorer** under **Scripts**.

To see the contents of the file, double-click **hubs**. If you are not using Visual Studio 2012 or 2013 and Internet Explorer, or if you are not in debug mode, you can also get the contents of the file by browsing to the "/signalR/hubs" URL. For example, if your site is running at `http://localhost:56699`, go to `http://localhost:56699/SignalR/hubs` in your browser.

How to create a physical file for the SignalR generated proxy

As an alternative to the dynamically generated proxy, you can create a physical file that has the proxy code and reference that file. You might want to do that for control over caching or bundling behavior, or to get IntelliSense when you are coding calls to server methods.

To create a proxy file, perform the following steps:

1. Install the Microsoft.AspNet.SignalR.Utils NuGet package.
2. Open a command prompt and browse to the *tools* folder that contains the SignalR.exe file. The tools folder is at the following location:

   `[your solution folder]\packages\Microsoft.AspNet.SignalR.Utils.2.1.0\tools`

3. Enter the following command:

   `signalr ghp /path:[path to the .dll that contains your Hub class]`

   The path to your *.dll* is typically the *bin* folder in your project folder.

   This command creates a file named *server.js* in the same folder as *signalr.exe*.

4. Put the *server.js* file in an appropriate folder in your project, rename it as appropriate for your application, and add a reference to it in place of the "signalr/hubs" reference.

How to establish a connection

Before you can establish a connection, you have to create a connection object, create a proxy, and register event handlers for methods that can be called from the server. When the proxy and event handlers are set up, establish the connection by calling the `start` method.

If you are using the generated proxy, you don't have to create the connection object in your own code because the generated proxy code does it for you.

Establish a connection (with the generated proxy)

```
var contosoChatHubProxy = $.connection.contosoChatHub;
contosoChatHubProxy.client.addContosoChatMessageToPage = function (name, message) {
    console.log(userName + ' ' + message);
};
$.connection.hub.start()
    .done(function(){ console.log('Now connected, connection ID=' + $.connection.hub.id); })
    .fail(function(){ console.log('Could not Connect!'); });
```

Establish a connection (without the generated proxy)

```
var connection = $.hubConnection();
var contosoChatHubProxy = connection.createHubProxy('contosoChatHub');
contosoChatHubProxy.on('addContosoChatMessageToPage', function(userName, message) {
    console.log(userName + ' ' + message);
});
connection.start()
    .done(function(){ console.log('Now connected, connection ID=' + connection.id); })
    .fail(function(){ console.log('Could not connect'); });
```

The sample code uses the default "/signalr" URL to connect to your SignalR service. For information about how to specify a different base URL, see ASP.NET SignalR Hubs API Guide - Server - The /signalr URL.

By default, the hub location is the current server; if you are connecting to a different server, specify the URL before calling the `start` method, as shown in the following example:

```
$.connection.hub.url = '<yourbackendurl>;
```

> **NOTE**
>
> Normally you register event handlers before calling the `start` method to establish the connection. If you want to register some event handlers after establishing the connection, you can do that, but you must register at least one of your event handler(s) before calling the `start` method. One reason for this is that there can be many Hubs in an application, but you wouldn't want to trigger the `OnConnected` event on every Hub if you are only going to use to one of them. When the connection is established, the presence of a client method on a Hub's proxy is what tells SignalR to trigger the `OnConnected` event. If you don't register any event handlers before calling the `start` method, you will be able to invoke methods on the Hub, but the Hub's `OnConnected` method won't be called and no client methods will be invoked from the server.

$.connection.hub is the same object that $.hubConnection() creates

As you can see from the examples, when you use the generated proxy, `$.connection.hub` refers to the connection object. This is the same object that you get by calling `$.hubConnection()` when you aren't using the generated

proxy. The generated proxy code creates the connection for you by executing the following statement:

```
// This line is at the end of the generated proxy code.
signalR.hub = $.hubConnection("/signalr", { useDefaultPath: false });
```

When you're using the generated proxy, you can do anything with `$.connection.hub` that you can do with a connection object when you're not using the generated proxy.

Asynchronous execution of the start method

The `start` method executes asynchronously. It returns a jQuery Deferred object, which means that you can add callback functions by calling methods such as `pipe`, `done`, and `fail`. If you have code that you want to execute after the connection is established, such as a call to a server method, put that code in a callback function or call it from a callback function. The `.done` callback method is executed after the connection has been established, and after any code that you have in your `OnConnected` event handler method on the server finishes executing.

If you put the "Now connected" statement from the preceding example as the next line of code after the `start` method call (not in a `.done` callback), the `console.log` line will execute before the connection is established, as shown in the following example:

```
$.connection.hub.start();
console.log("Now connected, connection ID=" + $.connection.hub.id);
```

How to establish a cross-domain connection

Typically if the browser loads a page from `http://contoso.com`, the SignalR connection is in the same domain, at `http://contoso.com/signalr`. If the page from `http://contoso.com` makes a connection to `http://fabrikam.com/signalr`, that is a cross-domain connection. For security reasons, cross-domain connections are disabled by default.

In SignalR 1.x, cross domain requests were controlled by a single EnableCrossDomain flag. This flag controlled both JSONP and CORS requests. For greater flexibility, all CORS support has been removed from the server component of SignalR (JavaScript clients still use CORS normally if it is detected that the browser supports it), and new OWIN middleware has been made available to support these scenarios.

If JSONP is required on the client (to support cross-domain requests in older browsers), it will need to be enabled explicitly by setting `EnableJSONP` on the `HubConfiguration` object to `true`, as shown below. JSONP is disabled by default, as it is less secure than CORS.

Adding Microsoft.Owin.Cors to your project: To install this library, run the following command in the Package Manager Console:

```
Install-Package Microsoft.Owin.Cors
```

This command will add the 2.1.0 version of the package to your project.

Calling UseCors

The following code snippet demonstrates how to implement cross-domain connections in SignalR 2.

Implementing cross-domain requests in SignalR 2

The following code demonstrates how to enable CORS or JSONP in a SignalR 2 project. This code sample uses `Map` and `RunSignalR` instead of `MapSignalR`, so that the CORS middleware runs only for the SignalR requests that require CORS support (rather than for all traffic at the path specified in `MapSignalR`.) Map can also be used for any other middleware that needs to run for a specific URL prefix, rather than for the entire application.

```
using Microsoft.AspNet.SignalR;
using Microsoft.Owin.Cors;
using Owin;
namespace MyWebApplication
{
    public class Startup
    {
        public void Configuration(IAppBuilder app)
        {
            // Branch the pipeline here for requests that start with "/signalr"
            app.Map("/signalr", map =>
            {
                // Setup the CORS middleware to run before SignalR.
                // By default this will allow all origins. You can
                // configure the set of origins and/or http verbs by
                // providing a cors options with a different policy.
                map.UseCors(CorsOptions.AllowAll);
                var hubConfiguration = new HubConfiguration
                {
                    // You can enable JSONP by uncommenting line below.
                    // JSONP requests are insecure but some older browsers (and some
                    // versions of IE) require JSONP to work cross domain
                    // EnableJSONP = true
                };
                // Run the SignalR pipeline. We're not using MapSignalR
                // since this branch already runs under the "/signalr"
                // path.
                map.RunSignalR(hubConfiguration);
            });
        }
    }
}
```

NOTE

- Don't set `jQuery.support.cors` to true in your code.

  ```
  // Don't put the following line in your code.
  jQuery.support.cors = true;
  $.connection.hub.start();
  ```

  SignalR handles the use of CORS. Setting `jQuery.support.cors` to true disables JSONP because it causes SignalR to assume the browser supports CORS.

- When you're connecting to a localhost URL, Internet Explorer 10 won't consider it a cross-domain connection, so the application will work locally with IE 10 even if you haven't enabled cross-domain connections on the server.
- For information about using cross-domain connections with Internet Explorer 9, see this StackOverflow thread.
- For information about using cross-domain connections with Chrome, see this StackOverflow thread.
- The sample code uses the default "/signalr" URL to connect to your SignalR service. For information about how to specify a different base URL, see ASP.NET SignalR Hubs API Guide - Server - The /signalr URL.

How to configure the connection

Before you establish a connection, you can specify query string parameters or specify the transport method.

How to specify query string parameters

If you want to send data to the server when the client connects, you can add query string parameters to the connection object. The following examples show how to set a query string parameter in client code.

Set a query string value before calling the start method (with the generated proxy)

```
$.connection.hub.qs = { 'version' : '1.0' };
```

Set a query string value before calling the start method (without the generated proxy)

```
var connection = $.hubConnection();
connection.qs = { 'version' : '1.0' };
```

The following example shows how to read a query string parameter in server code.

```
public class ContosoChatHub : Hub
{
    public override Task OnConnected()
    {
        var version = Context.QueryString['version'];
        if (version != '1.0')
        {
            Clients.Caller.notifyWrongVersion();
        }
        return base.OnConnected();
    }
}
```

How to specify the transport method

As part of the process of connecting, a SignalR client normally negotiates with the server to determine the best transport that is supported by both server and client. If you already know which transport you want to use, you can bypass this negotiation process by specifying the transport method when you call the `start` method.

Client code that specifies the transport method (with the generated proxy)

```
$.connection.hub.start( { transport: 'longPolling' });
```

Client code that specifies the transport method (without the generated proxy)

```
var connection = $.hubConnection();
connection.start({ transport: 'longPolling' });
```

As an alternative, you can specify multiple transport methods in the order in which you want SignalR to try them:

Client code that specifies a custom transport fallback scheme (with the generated proxy)

```
$.connection.hub.start( { transport: ['webSockets', 'longPolling'] });
```

Client code that specifies a custom transport fallback scheme (without the generated proxy)

```
var connection = $.hubConnection();
connection.start({ transport: ['webSockets', 'longPolling'] });
```

You can use the following values for specifying the transport method:

- "webSockets"
- "foreverFrame"
- "serverSentEvents"
- "longPolling"

The following examples show how to find out which transport method is being used by a connection.

Client code that displays the transport method used by a connection (with the generated proxy)

```
$.connection.hub.start().done(function () {
    console.log("Connected, transport = " + $.connection.hub.transport.name);
});
```

Client code that displays the transport method used by a connection (without the generated proxy)

```
var connection = $.hubConnection();
connection.hub.start().done(function () {
    console.log("Connected, transport = " + connection.transport.name);
});
```

For information about how to check the transport method in server code, see ASP.NET SignalR Hubs API Guide - Server - How to get information about the client from the Context property. For more information about transports and fallbacks, see Introduction to SignalR - Transports and Fallbacks.

How to get a proxy for a Hub class

Each connection object that you create encapsulates information about a connection to a SignalR service that contains one or more Hub classes. To communicate with a Hub class, you use a proxy object which you create yourself (if you're not using the generated proxy) or which is generated for you.

On the client the proxy name is a camel-cased version of the Hub class name. SignalR automatically makes this change so that JavaScript code can conform to JavaScript conventions.

Hub class on server

```
public class ContosoChatHub : Hub
```

Get a reference to the generated client proxy for the Hub

```
var myHubProxy = $.connection.contosoChatHub
```

Create client proxy for the Hub class (without generated proxy)

```
var contosoChatHubProxy = connection.createHubProxy('contosoChatHub');
```

If you decorate your Hub class with a `HubName` attribute, use the exact name without changing case.

Hub class on server with HubName attribute

```
[HubName("ContosoChatHub")]
public class ChatHub : Hub
```

Get a reference to the generated client proxy for the Hub

```
var contosoChatHubProxy = $.connection.ContosoChatHub
```

Create client proxy for the Hub class (without generated proxy)

```
var contosoChatHubProxy = connection.createHubProxy('ContosoChatHub');
```

How to define methods on the client that the server can call

To define a method that the server can call from a Hub, add an event handler to the Hub proxy by using the `client` property of the generated proxy, or call the `on` method if you aren't using the generated proxy. The parameters can be complex objects.

Add the event handler before you call the `start` method to establish the connection. (If you want to add event handlers after calling the `start` method, see the note in How to establish a connection earlier in this document, and use the syntax shown for defining a method without using the generated proxy.)

Method name matching is case-insensitive. For example, `Clients.All.addContosoChatMessageToPage` on the server will execute `AddContosoChatMessageToPage`, `addContosoChatMessageToPage`, or `addcontosochatmessagetopage` on the client.

Define method on client (with the generated proxy)

```
var contosoChatHubProxy = $.connection.contosoChatHub;
contosoChatHubProxy.client.addContosoChatMessageToPage = function (userName, message) {
    console.log(userName + ' ' + message);
};
$.connection.hub.start()
    .done(function(){ console.log('Now connected, connection ID=' + $.connection.hub.id); })
    .fail(function(){ console.log('Could not Connect!'); });
```

Alternate way to define method on client (with the generated proxy)

```
$.extend(contosoChatHubProxy.client, {
    addContosoChatMessageToPage: function(userName, message) {
    console.log(userName + ' ' + message);
    };
});
```

Define method on client (without the generated proxy, or when adding after calling the start method)

```
var connection = $.hubConnection();
var contosoChatHubProxy = connection.createHubProxy('contosoChatHub');
contosoChatHubProxy.on('addContosoChatMessageToPage', function(userName, message) {
    console.log(userName + ' ' + message);
});
connection.start()
    .done(function(){ console.log('Now connected, connection ID=' + connection.id); })
    .fail(function(){ console.log('Could not connect'); });
```

Server code that calls the client method

```
public class ContosoChatHub : Hub
{
    public void NewContosoChatMessage(string name, string message)
    {
        Clients.All.addContosoChatMessageToPage(name, message);
    }
}
```

The following examples include a complex object as a method parameter.

Define method on client that takes a complex object (with the generated proxy)

```
var contosoChatHubProxy = $.connection.contosoChatHub;
contosoChatHubProxy.client.addMessageToPage = function (message) {
    console.log(message.UserName + ' ' + message.Message);
});
```

Define method on client that takes a complex object (without the generated proxy)

```
var connection = $.hubConnection();
var contosoChatHubProxy = connection.createHubProxy('contosoChatHub');
chatHubProxy.on('addMessageToPage', function (message) {
    console.log(message.UserName + ' ' + message.Message);
});
```

Server code that defines the complex object

```
public class ContosoChatMessage
{
    public string UserName { get; set; }
    public string Message { get; set; }
}
```

Server code that calls the client method using a complex object

```
public void SendMessage(string name, string message)
{
    Clients.All.addContosoChatMessageToPage(new ContosoChatMessage() { UserName = name, Message = message });
}
```

How to call server methods from the client

To call a server method from the client, use the `server` property of the generated proxy or the `invoke` method on the Hub proxy if you aren't using the generated proxy. The return value or parameters can be complex objects.

Pass in a camel-case version of the method name on the Hub. SignalR automatically makes this change so that JavaScript code can conform to JavaScript conventions.

The following examples show how to call a server method that doesn't have a return value and how to call a server method that does have a return value.

Server method with no HubMethodName attribute

```
public class ContosoChatHub : Hub
{
    public void NewContosoChatMessage(ChatMessage message)
    {
        Clients.All.addContosoChatMessageToPage(message);
    }
}
```

Server code that defines the complex object passed in a parameter

```
public class ChatMessage
{
    public string UserName { get; set; }
    public string Message { get; set; }
}
```

Client code that invokes the server method (with the generated proxy)

```
contosoChatHubProxy.server.newContosoChatMessage({ UserName: userName, Message: message}).done(function () {
        console.log ('Invocation of NewContosoChatMessage succeeded');
    }).fail(function (error) {
        console.log('Invocation of NewContosoChatMessage failed. Error: ' + error);
    });
```

Client code that invokes the server method (without the generated proxy)

```
contosoChatHubProxy.invoke('newContosoChatMessage', { UserName: userName, Message: message}).done(function ()
{
        console.log ('Invocation of NewContosoChatMessage succeeded');
    }).fail(function (error) {
        console.log('Invocation of NewContosoChatMessage failed. Error: ' + error);
    });
```

If you decorated the Hub method with a `HubMethodName` attribute, use that name without changing case.

Server method with a HubMethodName attribute

```
public class ContosoChatHub : Hub
{
    [HubMethodName("NewContosoChatMessage")]
    public void NewContosoChatMessage(string name, string message)
    {
        Clients.All.addContosoChatMessageToPage(name, message);
    }
}
```

Client code that invokes the server method (with the generated proxy)

```
contosoChatHubProxy.server.NewContosoChatMessage(userName, message).done(function () {
        console.log ('Invocation of NewContosoChatMessage succeeded');
    }).fail(function (error) {
        console.log('Invocation of NewContosoChatMessage failed. Error: ' + error);
    });
```

Client code that invokes the server method (without the generated proxy)

```
contosoChatHubProxy.invoke('NewContosoChatMessage', userName, message).done(function () {
        console.log ('Invocation of NewContosoChatMessage succeeded');
    }).fail(function (error) {
        console.log('Invocation of NewContosoChatMessage failed. Error: ' + error);
    });
```

The preceding examples show how to call a server method that has no return value. The following examples show how to call a server method that has a return value.

Server code for a method that has a return value

```
public class StockTickerHub : Hub
{
    public IEnumerable<Stock> GetAllStocks()
    {
        return _stockTicker.GetAllStocks();
    }
}
```

The Stock class used for the return value

```
public class Stock
{
    public string Symbol { get; set; }
    public decimal Price { get; set; }
}
```

Client code that invokes the server method (with the generated proxy)

```
function init() {
    return stockTickerProxy.server.getAllStocks().done(function (stocks) {
        $.each(stocks, function () {
            var stock = this;
            console.log("Symbol=" + stock.Symbol + " Price=" + stock.Price);
        });
    }).fail(function (error) {
        console.log('Error: ' + error);
    });
}
```

Client code that invokes the server method (without the generated proxy)

```
function init() {
    return stockTickerProxy.invoke('getAllStocks').done(function (stocks) {
        $.each(stocks, function () {
            var stock = this;
            console.log("Symbol=" + stock.Symbol + " Price=" + stock.Price);
        });
    }).fail(function (error) {
        console.log('Error: ' + error);
    });
}
```

How to handle connection lifetime events

SignalR provides the following connection lifetime events that you can handle:

- `starting`: Raised before any data is sent over the connection.

- `received`: Raised when any data is received on the connection. Provides the received data.
- `connectionSlow`: Raised when the client detects a slow or frequently dropping connection.
- `reconnecting`: Raised when the underlying transport begins reconnecting.
- `reconnected`: Raised when the underlying transport has reconnected.
- `stateChanged`: Raised when the connection state changes. Provides the old state and the new state (Connecting, Connected, Reconnecting, or Disconnected).
- `disconnected`: Raised when the connection has disconnected.

For example, if you want to display warning messages when there are connection problems that might cause noticeable delays, handle the `connectionSlow` event.

Handle the connectionSlow event (with the generated proxy)

```
$.connection.hub.connectionSlow(function () {
    console.log('We are currently experiencing difficulties with the connection.')
});
```

Handle the connectionSlow event (without the generated proxy)

```
var connection = $.hubConnection();
connection.connectionSlow(function () {
    console.log('We are currently experiencing difficulties with the connection.')
});
```

For more information, see Understanding and Handling Connection Lifetime Events in SignalR.

How to handle errors

The SignalR JavaScript client provides an `error` event that you can add a handler for. You can also use the fail method to add a handler for errors that result from a server method invocation.

If you don't explicitly enable detailed error messages on the server, the exception object that SignalR returns after an error contains minimal information about the error. For example, if a call to `newContosoChatMessage` fails, the error message in the error object contains "`There was an error invoking Hub method 'contosoChatHub.newContosoChatMessage'.`" Sending detailed error messages to clients in production is not recommended for security reasons, but if you want to enable detailed error messages for troubleshooting purposes, use the following code on the server.

```
var hubConfiguration = new HubConfiguration();
hubConfiguration.EnableDetailedErrors = true;
app.MapSignalR(hubConfiguration);
```

The following example shows how to add a handler for the error event.

Add an error handler (with the generated proxy)

```
$.connection.hub.error(function (error) {
    console.log('SignalR error: ' + error)
});
```

Add an error handler (without the generated proxy)

```
var connection = $.hubConnection();
connection.error(function (error) {
    console.log('SignalR error: ' + error)
});
```

The following example shows how to handle an error from a method invocation.

Handle an error from a method invocation (with the generated proxy)

```
contosoChatHubProxy.newContosoChatMessage(userName, message)
    .fail(function(error) {
        console.log( 'newContosoChatMessage error: ' + error)
    });
```

Handle an error from a method invocation (without the generated proxy)

```
contosoChatHubProxy.invoke('newContosoChatMessage', userName, message)
    .fail(function(error) {
        console.log( 'newContosoChatMessage error: ' + error)
    });
```

If a method invocation fails, the `error` event is also raised, so your code in the `error` method handler and in the `.fail` method callback would execute.

How to enable client-side logging

To enable client-side logging on a connection, set the `logging` property on the connection object before you call the `start` method to establish the connection.

Enable logging (with the generated proxy)

```
$.connection.hub.logging = true;
$.connection.hub.start();
```

Enable logging (without the generated proxy)

```
var connection = $.hubConnection();
connection.logging = true;
connection.start();
```

To see the logs, open your browser's developer tools and go to the Console tab. For a tutorial that shows step-by-step instructions and screen shots that show how to do this, see Server Broadcast with ASP.NET Signalr - Enable Logging.

ASP.NET SignalR Hubs API Guide - .NET Client (C#)

2/20/2020 • 15 minutes to read • Edit Online

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This document provides an introduction to using the Hubs API for SignalR version 2 in .NET clients, such as Windows Store (WinRT), WPF, Silverlight, and console applications.

The SignalR Hubs API enables you to make remote procedure calls (RPCs) from a server to connected clients and from clients to the server. In server code, you define methods that can be called by clients, and you call methods that run on the client. In client code, you define methods that can be called from the server, and you call methods that run on the server. SignalR takes care of all of the client-to-server plumbing for you.

SignalR also offers a lower-level API called Persistent Connections. For an introduction to SignalR, Hubs, and Persistent Connections, or for a tutorial that shows how to build a complete SignalR application, see SignalR - Getting Started.

Software versions used in this topic

- Visual Studio 2017
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Overview

This document contains the following sections:

- Client Setup
- How to establish a connection
  - Cross-domain connections from Silverlight clients
- How to configure the connection
  - How to set the maximum number of concurrent connections in WPF clients
  - How to specify query string parameters
  - How to specify the transport method
  - How to specify HTTP headers

- How to specify client certificates
- How to create the Hub proxy
- How to define methods on the client that the server can call
  - Methods without parameters
  - Methods with parameters, specifying parameter types
  - Methods with parameters, specifying dynamic objects for the parameters
  - How to remove a handler
- How to call server methods from the client
- How to handle connection lifetime events
- How to handle errors
- How to enable client-side logging
- WPF, Silverlight, and console application code samples for client methods that the server can call

For a sample .NET client projects, see the following resources:

- gustavo-armenta / SignalR-Samples on GitHub.com (WinRT, Silverlight, console app examples).
- DamianEdwards / SignalR-MoveShapeDemo / MoveShape.Desktop on GitHub.com (WPF example).
- SignalR / Microsoft.AspNet.SignalR.Client.Samples on GitHub.com (Console app example).

For documentation on how to program the server or JavaScript clients, see the following resources:

- SignalR Hubs API Guide - Server
- SignalR Hubs API Guide - JavaScript Client

Links to API Reference topics are to the .NET 4.5 version of the API. If you're using .NET 4, see the .NET 4 version of the API topics.

Client setup

Install the Microsoft.AspNet.SignalR.Client NuGet package (not the Microsoft.AspNet.SignalR package). This package supports WinRT, Silverlight, WPF, console application, and Windows Phone clients, for both .NET 4 and .NET 4.5.

If the version of SignalR that you have on the client is different from the version that you have on the server, SignalR is often able to adapt to the difference. For example, a server running SignalR version 2 will support clients that have 1.1.x installed as well as clients that have version 2 installed. If the difference between the version on the server and the version on the client is too great, or if the client is newer than the server, SignalR throws an `InvalidOperationException` exception when the client tries to establish a connection. The error message is "

```
You are using a version of the client that isn't compatible with the server. Client version X.X, server version X.X
```

".

How to establish a connection

Before you can establish a connection, you have to create a `HubConnection` object and create a proxy. To establish the connection, call the `Start` method on the `HubConnection` object.

```
using (var hubConnection = new HubConnection("http://www.contoso.com/"))
{
    IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
    stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new
price {1}", stock.Symbol, stock.Price));
    await hubConnection.Start();
}
```

> **NOTE**
>
> For JavaScript clients you have to register at least one event handler before calling the `Start` method to establish the connection. This is not necessary for .NET clients. For JavaScript clients, the generated proxy code automatically creates proxies for all Hubs that exist on the server, and registering a handler is how you indicate which Hubs your client intends to use. But for a .NET client you create Hub proxies manually, so SignalR assumes that you will be using any Hub that you create a proxy for.

The sample code uses the default "/signalr" URL to connect to your SignalR service. For information about how to specify a different base URL, see ASP.NET SignalR Hubs API Guide - Server - The /signalr URL.

The `Start` method executes asynchronously. To make sure that subsequent lines of code don't execute until after the connection is established, use `await` in an ASP.NET 4.5 asynchronous method or `.Wait()` in a synchronous method. Don't use `.Wait()` in a WinRT client.

```
await connection.Start();
```

```
connection.Start().Wait();
```

Cross-domain connections from Silverlight clients

For information about how to enable cross-domain connections from Silverlight clients, see Making a Service Available Across Domain Boundaries.

How to configure the connection

Before you establish a connection, you can specify any of the following options:

- Concurrent connections limit.
- Query string parameters.
- The transport method.
- HTTP headers.
- Client certificates.

How to set the maximum number of concurrent connections in WPF clients

In WPF clients, you might have to increase the maximum number of concurrent connections from its default value of 2. The recommended value is 10.

```
using (var hubConnection = new HubConnection("http://www.contoso.com/"))
{
    IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
    stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new
price {1}", stock.Symbol, stock.Price));
    ServicePointManager.DefaultConnectionLimit = 10;
    await hubConnection.Start();
}
```

For more information, see ServicePointManager.DefaultConnectionLimit.

How to specify query string parameters

If you want to send data to the server when the client connects, you can add query string parameters to the connection object. The following example shows how to set a query string parameter in client code.

```
var querystringData = new Dictionary<string, string>();
querystringData.Add("contosochatversion", "1.0");
var connection = new HubConnection("http://contoso.com/", querystringData);
```

The following example shows how to read a query string parameter in server code.

```
public class StockTickerHub : Hub
{
    public override Task OnConnected()
    {
        var version = Context.QueryString["contosochatversion"];
        if (version != "1.0")
        {
            Clients.Caller.notifyWrongVersion();
        }
        return base.OnConnected();
    }
}
```

How to specify the transport method

As part of the process of connecting, a SignalR client normally negotiates with the server to determine the best transport that is supported by both server and client. If you already know which transport you want to use, you can bypass this negotiation process. To specify the transport method, pass in a transport object to the Start method. The following example shows how to specify the transport method in client code.

```
using (var hubConnection = new HubConnection("http://www.contoso.com/"))
{
    IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
    stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new
price {1}", stock.Symbol, stock.Price));
    await hubConnection.Start(new LongPollingTransport());
}
```

The Microsoft.AspNet.SignalR.Client.Transports namespace includes the following classes that you can use to specify the transport.

- LongPollingTransport
- ServerSentEventsTransport
- WebSocketTransport (Available only when both server and client use .NET 4.5.)
- AutoTransport (Automatically chooses the best transport that is supported by both the client and the server. This is the default transport. Passing this in to the `Start` method has the same effect as not passing in

anything.)

The ForeverFrame transport is not included in this list because it is used only by browsers.

For information about how to check the transport method in server code, see ASP.NET SignalR Hubs API Guide - Server - How to get information about the client from the Context property. For more information about transports and fallbacks, see Introduction to SignalR - Transports and Fallbacks.

How to specify HTTP headers

To set HTTP headers, use the `Headers` property on the connection object. The following example shows how to add an HTTP header.

```
hubConnection = new hubConnection("http://www.contoso.com/");
connection.Headers.Add("headername", "headervalue");
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price
{1}", stock.Symbol, stock.Price));
await connection.Start();
```

How to specify client certificates

To add client certificates, use the `AddClientCertificate` method on the connection object.

```
hubConnection = new hubConnection("http://www.contoso.com/");
hubConnection.AddClientCertificate(X509Certificate.CreateFromCertFile("MyCert.cer"));
IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new price
{1}", stock.Symbol, stock.Price));
await connection.Start();
```

How to create the Hub proxy

In order to define methods on the client that a Hub can call from the server, and to invoke methods on a Hub at the server, create a proxy for the Hub by calling `CreateHubProxy` on the connection object. The string you pass in to `CreateHubProxy` is the name of your Hub class, or the name specified by the `HubName` attribute if one was used on the server. Name matching is case-insensitive.

Hub class on server

```
public class StockTickerHub : Hub
```

Create client proxy for the Hub class

```
using (var hubConnection = new HubConnection("http://www.contoso.com/"))
{
    IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
    stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new
price {1}", stock.Symbol, stock.Price));
    await hubConnection.Start();
}
```

If you decorate your Hub class with a `HubName` attribute, use that name.

Hub class on server

```
[HubName("stockTicker")]
public class StockTickerHub : Hub
```

Create client proxy for the Hub class

```
using (var hubConnection = new HubConnection("http://www.contoso.com/"))
{
    IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("stockTicker");
    stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
        Console.WriteLine("Stock update for {0} new price {1}", stock.Symbol, stock.Price));
    await hubConnection.Start();
}
```

If you call `HubConnection.CreateHubProxy` multiple times with the same `hubName`, you get the same cached `IHubProxy` object.

How to define methods on the client that the server can call

To define a method that the server can call, use the proxy's `On` method to register an event handler.

Method name matching is case-insensitive. For example, `Clients.All.UpdateStockPrice` on the server will execute `updateStockPrice`, `updatestockprice`, or `UpdateStockPrice` on the client.

Different client platforms have different requirements for how you write method code to update the UI. The examples shown are for WinRT (Windows Store .NET) clients. WPF, Silverlight, and console application examples are provided in a separate section later in this topic.

Methods without parameters

If the method you're handling does not have parameters, use the non-generic overload of the `On` method:

Server code calling client method without parameters

```
public class StockTickerHub : Hub
{
    public void NotifyAllClients()
    {
         Clients.All.Notify();
    }
}
```

WinRT Client code for method called from server without parameters (see WPF and Silverlight examples later in this topic)

```
using (var hubConnection = new HubConnection("http://www.contoso.com/"))
{
    IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
    stockTickerHub.On("notify", () =>
        // Context is a reference to SynchronizationContext.Current
        Context.Post(delegate
        {
            textBox.Text += "Notified!\n";
        }, null)
    );
    await hubConnection.Start();
}
```

Methods with parameters, specifying the parameter types

If the method you're handling has parameters, specify the types of the parameters as the generic types of the `On` method. There are generic overloads of the `On` method to enable you to specify up to 8 parameters (4 on Windows Phone 7). In the following example, one parameter is sent to the `UpdateStockPrice` method.

Server code calling client method with a parameter

```
public void BroadcastStockPrice(Stock stock)
{
    context.Clients.Others.UpdateStockPrice(stock);
}
```

The Stock class used for the parameter

```
public class Stock
{
    public string Symbol { get; set; }
    public decimal Price { get; set; }
}
```

WinRT Client code for a method called from server with a parameter (see WPF and Silverlight examples later in this topic)

```
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
    }, null)
);
```

Methods with parameters, specifying dynamic objects for the parameters

As an alternative to specifying parameters as generic types of the `On` method, you can specify parameters as dynamic objects:

Server code calling client method with a parameter

```
public void BroadcastStockPrice(Stock stock)
{
    context.Clients.Others.UpdateStockPrice(stock);
}
```

The Stock class used for the parameter

```
public class Stock
{
    public string Symbol { get; set; }
    public decimal Price { get; set; }
}
```

WinRT Client code for a method called from server with a parameter, using a dynamic object for the parameter (see WPF and Silverlight examples later in this topic)

```
stockTickerHubProxy.On("UpdateStockPrice", stock =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
    }, null)
);
```

How to remove a handler

To remove a handler, call its `Dispose` method.

Client code for a method called from server

```
var updateStockPriceHandler = stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    Context.Post(delegate
    {
        textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
    }, null)
);
```

Client code to remove the handler

```
updateStockPriceHandler.Dispose();
```

How to call server methods from the client

To call a method on the server, use the `Invoke` method on the Hub proxy.

If the server method has no return value, use the non-generic overload of the `Invoke` method.

Server code for a method that has no return value

```
public class StockTickerHub : Hub
{
    public void JoinGroup(string groupName)
    {
        Groups.Add(Context.ConnectionId, groupName);
    }
}
```

Client code calling a method that has no return value

```
stockTickerHubProxy.Invoke("JoinGroup", "SignalRChatRoom");
```

If the server method has a return value, specify the return type as the generic type of the `Invoke` method.

Server code for a method that has a return value and takes a complex type parameter

```
public IEnumerable<Stock> AddStock(Stock stock)
{
    _stockTicker.AddStock(stock);
    return _stockTicker.GetAllStocks();
}
```

The Stock class used for the parameter and return value

```
public class Stock
{
    public string Symbol { get; set; }
    public decimal Price { get; set; }
}
```

Client code calling a method that has a return value and takes a complex type parameter, in an ASP.NET 4.5 async method

```
var stocks = await stockTickerHub.Invoke<IEnumerable<Stock>>("AddStock", new Stock() { Symbol = "MSFT" });
foreach (Stock stock in stocks)
{
    textBox.Text += string.Format("Symbol: {0} price: {1}\n", stock.Symbol, stock.Price);
}
```

Client code calling a method that has a return value and takes a complex type parameter, in a synchronous method

```
var stocks = stockTickerHub.Invoke<IEnumerable<Stock>>("AddStock", new Stock() { Symbol = "MSFT" }).Result;
foreach (Stock stock in stocks)
{
    textBox.Text += string.Format("Symbol: {0} price: {1}\n", stock.Symbol, stock.Price);
}
```

The `Invoke` method executes asynchronously and returns a `Task` object. If you don't specify `await` or `.Wait()`, the next line of code will execute before the method that you invoke has finished executing.

How to handle connection lifetime events

SignalR provides the following connection lifetime events that you can handle:

- `Received`: Raised when any data is received on the connection. Provides the received data.
- `ConnectionSlow`: Raised when the client detects a slow or frequently dropping connection.
- `Reconnecting`: Raised when the underlying transport begins reconnecting.
- `Reconnected`: Raised when the underlying transport has reconnected.
- `StateChanged`: Raised when the connection state changes. Provides the old state and the new state. For information about connection state values see ConnectionState Enumeration.
- `Closed`: Raised when the connection has disconnected.

For example, if you want to display warning messages for errors that are not fatal but cause intermittent connection problems, such as slowness or frequent dropping of the connection, handle the `ConnectionSlow` event.

```
hubConnection.ConnectionSlow += () => Console.WriteLine("Connection problems.");
```

For more information, see Understanding and Handling Connection Lifetime Events in SignalR.

How to handle errors

If you don't explicitly enable detailed error messages on the server, the exception object that SignalR returns after an error contains minimal information about the error. For example, if a call to `newContosoChatMessage` fails, the error message in the error object contains "
`There was an error invoking Hub method 'contosoChatHub.newContosoChatMessage'.`" Sending detailed error

messages to clients in production is not recommended for security reasons, but if you want to enable detailed error messages for troubleshooting purposes, use the following code on the server.

```
var hubConfiguration = new HubConfiguration();
hubConfiguration.EnableDetailedErrors = true;
App.MapSignalR(hubConfiguration);
```

To handle errors that SignalR raises, you can add a handler for the `Error` event on the connection object.

```
hubConnection.Error += ex => Console.WriteLine("SignalR error: {0}", ex.Message);
```

To handle errors from method invocations, wrap the code in a try-catch block.

```
try
{
    IEnumerable<Stock> stocks = await stockTickerHub.Invoke<IEnumerable<Stock>>("GetAllStocks");
    foreach (Stock stock in stocks)
    {
        Console.WriteLine("Symbol: {0} price: {1}", stock.Symbol, stock.Price);
    }
}
catch (Exception ex)
{
    Console.WriteLine("Error invoking GetAllStocks: {0}", ex.Message);
}
```

How to enable client-side logging

To enable client-side logging, set the `TraceLevel` and `TraceWriter` properties on the connection object.

```
using (var hubConnection = new HubConnection("http://www.contoso.com/"))
{
    hubConnection.TraceLevel = TraceLevels.All;
    hubConnection.TraceWriter = Console.Out;
    IHubProxy stockTickerHubProxy = hubConnection.CreateHubProxy("StockTickerHub");
    stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock => Console.WriteLine("Stock update for {0} new
price {1}", stock.Symbol, stock.Price));
    await hubConnection.Start();
}
```

WPF, Silverlight, and console application code samples for client methods that the server can call

The code samples shown earlier for defining client methods that the server can call apply to WinRT clients. The following samples show the equivalent code for WPF, Silverlight, and console application clients.

Methods without parameters

WPF client code for method called from server without parameters

```
stockTickerHub.On<Stock>("notify", () =>
    Dispatcher.InvokeAsync(() =>
        {
            SignalRTextBlock.Text += string.Format("Notified!");
        })
);
```

Silverlight client code for method called from server without parameters

```
stockTickerHub.On<Stock>("notify", () =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += "Notified!";
    }, null)
);
```

Console application client code for method called from server without parameters

```
stockTickerHubProxyProxy.On("Notify", () => Console.WriteLine("Notified!"));
```

Methods with parameters, specifying the parameter types

WPF client code for a method called from server with a parameter

```
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    Dispatcher.InvokeAsync(() =>
        {
            textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
        })
);
```

Silverlight client code for a method called from server with a parameter

```
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
    }, null)
);
```

Console application client code for a method called from server with a parameter

```
stockTickerHubProxy.On<Stock>("UpdateStockPrice", stock =>
    Console.WriteLine("Symbol {0} Price {1}", stock.Symbol, stock.Price));
```

Methods with parameters, specifying dynamic objects for the parameters

WPF client code for a method called from server with a parameter, using a dynamic object for the parameter

```
stockTickerHubProxy.On("UpdateStockPrice", stock =>
    Dispatcher.InvokeAsync(() =>
        {
            textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
        })
);
```

Silverlight client code for a method called from server with a parameter, using a dynamic object for the parameter

```
stockTickerHubProxy.On("UpdateStockPrice", stock =>
    // Context is a reference to SynchronizationContext.Current
    Context.Post(delegate
    {
        textBox.Text += string.Format("Stock update for {0} new price {1}\n", stock.Symbol, stock.Price);
    }, null)
);
```

Console application client code for a method called from server with a parameter, using a dynamic object for the parameter

```
stockTickerHubProxy.On("UpdateStockPrice", stock =>
    Console.WriteLine("Symbol {0} Price {1}", stock.Symbol, stock.Price));
```

Understanding and Handling Connection Lifetime Events in SignalR

2/20/2020 • 17 minutes to read • Edit Online

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This article provides an overview of the SignalR connection, reconnection, and disconnection events that you can handle, and timeout and keepalive settings that you can configure.

The article assumes you already have some knowledge of SignalR and connection lifetime events. For an introduction to SignalR, see Introduction to SignalR. For lists of connection lifetime events, see the following resources:

- How to handle connection lifetime events in the Hub class
- How to handle connection lifetime events in JavaScript clients
- How to handle connection lifetime events in .NET clients

Software versions used in this topic

- Visual Studio 2017
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Overview

This article contains the following sections:

- Connection lifetime terminology and scenarios
  - SignalR connections, transport connections, and physical connections
  - Transport disconnection scenarios
  - Client disconnection scenarios
  - Server disconnection scenarios
- Timeout and keepalive settings
  - ConnectionTimeout

- DisconnectTimeout
- KeepAlive
- How to change timeout and keepalive settings

- How to notify the user about disconnections
- How to continuously reconnect
- How to disconnect a client in server code
- Detecting the reason for a disconnection

Links to API Reference topics are to the .NET 4.5 version of the API. If you're using .NET 4, see the .NET 4 version of the API topics.

Connection lifetime terminology and scenarios

The `OnReconnected` event handler in a SignalR Hub can execute directly after `OnConnected` but not after `OnDisconnected` for a given client. The reason you can have a reconnection without a disconnection is that there are several ways in which the word "connection" is used in SignalR.

SignalR connections, transport connections, and physical connections

This article will differentiate between *SignalR connections*, *transport connections*, and *physical connections*:

- **SignalR connection** refers to a logical relationship between a client and a server URL, maintained by the SignalR API and uniquely identified by a connection ID. The data about this relationship is maintained by SignalR and is used to establish a transport connection. The relationship ends and SignalR disposes of the data when the client calls the `Stop` method or a timeout limit is reached while SignalR is attempting to re-establish a lost transport connection.
- **Transport connection** refers to a logical relationship between a client and a server, maintained by one of the four transport APIs: WebSockets, server-sent events, forever frame, or long polling. SignalR uses the transport API to create a transport connection, and the transport API depends on the existence of a physical network connection to create the transport connection. The transport connection ends when SignalR terminates it or when the transport API detects that the physical connection is broken.
- **Physical connection** refers to the physical network links -- wires, wireless signals, routers, etc. -- that facilitate communication between a client computer and a server computer. The physical connection must be present in order to establish a transport connection, and a transport connection must be established in order to establish a SignalR connection. However, breaking the physical connection doesn't always immediately end the transport connection or the SignalR connection, as will be explained later in this topic.

In the following diagram, the SignalR connection is represented by the Hubs API and PersistentConnection API SignalR layer, the transport connection is represented by the Transports layer, and the physical connection is represented by the lines between the server and the clients.

When you call the `Start` method in a SignalR client, you are providing SignalR client code with all the information it needs in order to establish a physical connection to a server. SignalR client code uses this information to make an HTTP request and establish a physical connection that uses one of the four transport methods. If the transport connection fails or the server fails, the SignalR connection doesn't go away immediately because the client still has the information it needs to automatically re-establish a new transport connection to the same SignalR URL. In this scenario, no intervention from the user application is involved, and when the SignalR client code establishes a new transport connection, it does not start a new SignalR connection. The continuity of the SignalR connection is reflected in the fact that the connection ID, which is created when you call the `Start` method, does not change.

The `OnReconnected` event handler on the Hub executes when a transport connection is automatically re-established after having been lost. The `OnDisconnected` event handler executes at the end of a SignalR connection. A SignalR connection can end in any of the following ways:

- If the client calls the `Stop` method, a stop message is sent to the server, and both client and server end the SignalR connection immediately.
- After connectivity between client and server is lost, the client tries to reconnect and the server waits for the client to reconnect. If the attempts to reconnect are unsuccessful and the disconnect timeout period ends, both client and server end the SignalR connection. The client stops trying to reconnect, and the server disposes of its representation of the SignalR connection.
- If the client stops running without having a chance to call the `Stop` method, the server waits for the client to reconnect, and then ends the SignalR connection after the disconnect timeout period.
- If the server stops running, the client tries to reconnect (re-create the transport connection), and then ends the SignalR connection after the disconnect timeout period.

When there are no connection problems, and the user application ends the SignalR connection by calling the `Stop` method, the SignalR connection and the transport connection begin and end at about the same time. The following sections describe in more detail the other scenarios.

Transport disconnection scenarios

Physical connections might be slow or there might be interruptions in connectivity. Depending on factors such as the length of the interruption, the transport connection might be dropped. SignalR then tries to re-establish the transport connection. Sometimes the transport connection API detects the interruption and drops the transport connection, and SignalR finds out immediately that the connection is lost. In other scenarios, neither the transport connection API nor SignalR becomes aware immediately that connectivity has been lost. For all transports except long polling, the SignalR client uses a function called *keepalive* to check for loss of connectivity that the transport API is unable to detect. For information about long polling connections, see Timeout and keepalive settings later in this topic.

When a connection is inactive, periodically the server sends a keepalive packet to the client. As of the date this

article is being written, the default frequency is every 10 seconds. By listening for these packets, clients can tell if there is a connection problem. If a keepalive packet is not received when expected, after a short time the client assumes that there are connection problems such as slowness or interruptions. If the keepalive is still not received after a longer time, the client assumes that the connection has been dropped, and it begins trying to reconnect.

The following diagram illustrates the client and server events that are raised in a typical scenario when there are problems with the physical connection that aren't immediately recognized by the transport API. The diagram applies to the following circumstances:

- The transport is WebSockets, forever frame, or server-sent events.
- There are varying periods of interruption in the physical network connection.
- The transport API does not become aware of the interruptions, so SignalR relies on the keepalive functionality to detect them.

If the client goes into reconnecting mode but can't establish a transport connection within the disconnect timeout limit, the server terminates the SignalR connection. When that happens, the server executes the Hub's `OnDisconnected` method and queues up a disconnect message to send to the client in case the client manages to connect later. If the client then does reconnect, it receives the disconnect command and calls the `Stop` method. In this scenario, `OnReconnected` is not executed when the client reconnects, and `OnDisconnected` is not executed when the client calls `Stop`. The following diagram illustrates this scenario.

The SignalR connection lifetime events that may be raised on the client are the following:

- `ConnectionSlow` client event.

  Raised when a preset proportion of the keepalive timeout period has passed since the last message or keepalive ping was received. The default keepalive timeout warning period is 2/3 of the keepalive timeout. The keepalive timeout is 20 seconds, so the warning occurs at about 13 seconds.

By default, the server sends keepalive pings every 10 seconds, and the client checks for keepalive pings about every 2 seconds (one third of the difference between the keepalive timeout value and the keepalive timeout warning value).

If the transport API becomes aware of a disconnection, SignalR might be informed of the disconnection before the keepalive timeout warning period passes. In that case, the `ConnectionSlow` event would not be raised, and SignalR would go directly to the `Reconnecting` event.

- `Reconnecting` client event.

  Raised when (a) the transport API detects that the connection is lost, or (b) the keepalive timeout period has passed since the last message or keepalive ping was received. The SignalR client code begins trying to reconnect. You can handle this event if you want your application to take some action when a transport connection is lost. The default keepalive timeout period is currently 20 seconds.

  If your client code tries to call a Hub method while SignalR is in reconnecting mode, SignalR will try to send the command. Most of the time, such attempts will fail, but in some circumstances they might succeed. For the server-sent events, forever frame, and long polling transports, SignalR uses two communication channels, one that the client uses to send messages and one that it uses to receive messages. The channel used for receiving is the permanently open one, and that's the one that is closed when the physical connection is interrupted. The channel used for sending remains available, so if physical connectivity is restored, a method call from client to server might be successful before the receive channel is re-established. The return value would not be received until SignalR re-opens the channel used for receiving.

- `Reconnected` client event.

  Raised when the transport connection is reestablished. The `OnReconnected` event handler in the Hub executes.

- `Closed` client event (`disconnected` event in JavaScript).

  Raised when the disconnect timeout period expires while the SignalR client code is trying to reconnect after losing the transport connection. The default disconnect timeout is 30 seconds. (This event is also raised when the connection ends because the `Stop` method is called.)

Transport connection interruptions that are not detected by the transport API and don't delay the reception of keepalive pings from the server for longer than the keepalive timeout warning period might not cause any connection lifetime events to be raised.

Some network environments deliberately close idle connections, and another function of the keepalive packets is to help prevent this by letting these networks know that a SignalR connection is in use. In extreme cases the default frequency of keepalive pings might not be enough to prevent closed connections. In that case you can configure keepalive pings to be sent more often. For more information, see Timeout and keepalive settings later in this topic.

> **NOTE**
>
> **Important**: The sequence of events described here is not guaranteed. SignalR makes every attempt to raise connection lifetime events in a predictable manner according to this scheme, but there are many variations of network events and many ways in which underlying communications frameworks such as transport APIs handle them. For example, the `Reconnected` event might not be raised when the client reconnects, or the `OnConnected` handler on the server might run when the attempt to establish a connection is unsuccessful. This topic describes only the effects that would normally be produced by certain typical circumstances.

Client disconnection scenarios

In a browser client, the SignalR client code that maintains a SignalR connection runs in the JavaScript context of a web page. That's why the SignalR connection has to end when you navigate from one page to another, and that's why you have multiple connections with multiple connection IDs if you connect from multiple browser windows or tabs. When the user closes a browser window or tab, or navigates to a new page or refreshes the page, the SignalR connection immediately ends because SignalR client code handles that browser event for you and calls the `Stop` method. In these scenarios, or in any client platform when your application calls the `Stop` method, the `OnDisconnected` event handler executes immediately on the server and the client raises the `Closed` event (the event is named `disconnected` in JavaScript).

If a client application or the computer that it's running on crashes or goes to sleep (for example, when the user closes the laptop), the server is not informed about what happened. As far as the server knows, the loss of the client might be due to connectivity interruption and the client might be trying to reconnect. Therefore, in these scenarios the server waits to give the client a chance to reconnect, and `OnDisconnected` does not execute until the disconnect timeout period expires (about 30 seconds by default). The following diagram illustrates this scenario.

Server disconnection scenarios

When a server goes offline -- it reboots, fails, the app domain recycles, etc. -- the result might be similar to a lost connection, or the transport API and SignalR might know immediately that the server is gone, and SignalR might begin trying to reconnect without raising the `ConnectionSlow` event. If the client goes into reconnecting mode, and if the server recovers or restarts or a new server is brought online before the disconnect timeout period expires, the client will reconnect to the restored or new server. In that case, the SignalR connection continues on the client and the `Reconnected` event is raised. On the first server, `OnDisconnected` is never executed, and on the new server, `OnReconnected` is executed although `OnConnected` was never executed for that client on that server before. (The effect is the same if the client reconnects to the same server after a reboot or app domain recycle, because when the server restarts it has no memory of prior connection activity.) The following diagram assumes that the transport API becomes aware of the lost connection immediately, so the `ConnectionSlow` event is not raised.

If a server does not become available within the disconnect timeout period, the SignalR connection ends. In this scenario, the `Closed` event (`disconnected` in JavaScript clients) is raised on the client but `OnDisconnected` is never called on the server. The following diagram assumes that the transport API does not become aware of the

lost connection, so it is detected by SignalR keepalive functionality and the `ConnectionSlow` event is raised.

Timeout and keepalive settings

The default `ConnectionTimeout`, `DisconnectTimeout`, and `KeepAlive` values are appropriate for most scenarios but can be changed if your environment has special needs. For example, if your network environment closes connections that are idle for 5 seconds, you might have to decrease the keepalive value.

ConnectionTimeout

This setting represents the amount of time to leave a transport connection open and waiting for a response before closing it and opening a new connection. The default value is 110 seconds.

This setting applies only when keepalive functionality is disabled, which normally applies only to the long polling transport. The following diagram illustrates the effect of this setting on a long polling transport connection.

DisconnectTimeout

This setting represents the amount of time to wait after a transport connection is lost before raising the `Disconnected` event. The default value is 30 seconds. When you set `DisconnectTimeout`, `KeepAlive` is automatically set to 1/3 of the `DisconnectTimeout` value.

KeepAlive

This setting represents the amount of time to wait before sending a keepalive packet over an idle connection. The default value is 10 seconds. This value must not be more than 1/3 of the `DisconnectTimeout` value.

If you want to set both `DisconnectTimeout` and `KeepAlive`, set `KeepAlive` after `DisconnectTimeout`. Otherwise your `KeepAlive` setting will be overwritten when `DisconnectTimeout` automatically sets `KeepAlive` to 1/3 of the timeout value.

If you want to disable keepalive functionality, set `KeepAlive` to null. Keepalive functionality is automatically disabled for the long polling transport.

How to change timeout and keepalive settings

To change the default values for these settings, set them in `Application_Start` in your *Global.asax* file, as shown in the following example. The values shown in the sample code are the same as the default values.

```
protected void Application_Start(object sender, EventArgs e)
{
    // Make long polling connections wait a maximum of 110 seconds for a
    // response. When that time expires, trigger a timeout command and
    // make the client reconnect.
    GlobalHost.Configuration.ConnectionTimeout = TimeSpan.FromSeconds(110);

    // Wait a maximum of 30 seconds after a transport connection is lost
    // before raising the Disconnected event to terminate the SignalR connection.
    GlobalHost.Configuration.DisconnectTimeout = TimeSpan.FromSeconds(30);

    // For transports other than long polling, send a keepalive packet every
    // 10 seconds.
    // This value must be no more than 1/3 of the DisconnectTimeout value.
    GlobalHost.Configuration.KeepAlive = TimeSpan.FromSeconds(10);

    RouteTable.Routes.MapHubs();
}
```

How to notify the user about disconnections

In some applications you might want to display a message to the user when there are connectivity problems. You have several options for how and when to do this. The following code samples are for a JavaScript client using the generated proxy.

- Handle the `connectionSlow` event to display a message as soon as SignalR is aware of connection problems, before it goes into reconnecting mode.

  ```
  $.connection.hub.connectionSlow(function() {
      notifyUserOfConnectionProblem(); // Your function to notify user.
  });
  ```

- Handle the `reconnecting` event to display a message when SignalR is aware of a disconnection and is going into reconnecting mode.

  ```
  $.connection.hub.reconnecting(function() {
      notifyUserOfTryingToReconnect(); // Your function to notify user.
  });
  ```

- Handle the `disconnected` event to display a message when an attempt to reconnect has timed out. In this scenario, the only way to re-establish a connection with the server again is to restart the SignalR connection by calling the `Start` method, which will create a new connection ID. The following code sample uses a flag to make sure that you issue the notification only after a reconnecting timeout, not after a normal end to the SignalR connection caused by calling the `Stop` method.

```
var tryingToReconnect = false;

$.connection.hub.reconnecting(function() {
    tryingToReconnect = true;
});

$.connection.hub.reconnected(function() {
    tryingToReconnect = false;
});

$.connection.hub.disconnected(function() {
    if(tryingToReconnect) {
        notifyUserOfDisconnect(); // Your function to notify user.
    }
});
```

How to continuously reconnect

In some applications you might want to automatically re-establish a connection after it has been lost and the attempt to reconnect has timed out. To do that, you can call the `Start` method from your `Closed` event handler (`disconnected` event handler on JavaScript clients). You might want to wait a period of time before calling `Start` in order to avoid doing this too frequently when the server or the physical connection are unavailable. The following code sample is for a JavaScript client using the generated proxy.

```
$.connection.hub.disconnected(function() {
   setTimeout(function() {
       $.connection.hub.start();
   }, 5000); // Restart connection after 5 seconds.
});
```

A potential problem to be aware of in mobile clients is that continuous reconnection attempts when the server or physical connection isn't available could cause unnecessary battery drain.

How to disconnect a client in server code

SignalR version 2 does not have a built-in server API for disconnecting clients. There are plans for adding this functionality in the future. In the current SignalR release, the simplest way to disconnect a client from the server is to implement a disconnect method on the client and call that method from the server. The following code sample shows a disconnect method for a JavaScript client using the generated proxy.

```
var myHubProxy = $.connection.myHub
myHubProxy.client.stopClient = function() {
    $.connection.hub.stop();
};
```

WARNING

Security - Neither this method for disconnecting clients nor the proposed built-in API will address the scenario of hacked clients that are running malicious code, since the clients could reconnect or the hacked code might remove the `stopClient` method or change what it does. The appropriate place to implement stateful denial-of-service (DOS) protection is not in the framework or the server layer, but rather in front-end infrastructure.

Detecting the reason for a disconnection

SignalR 2.1 adds an overload to the server `OnDisconnect` event that indicates if the client deliberately disconnected rather than timing out. The `StopCalled` parameter is true if the client explicitly closed the connection. In JavaScript, if a server error led the client to disconnect, the error information will be passed to the client as `$.connection.hub.lastError`.

C# server code: `stopCalled` parameter

```
public override System.Threading.Tasks.Task OnDisconnected(bool stopCalled)
{
    if (stopCalled)
    {
        Console.WriteLine(String.Format("Client {0} explicitly closed the connection.",
Context.ConnectionId));
    }
    else
    {
        Console.WriteLine(String.Format("Client {0} timed out .", Context.ConnectionId));
    }

    return base.OnDisconnected(stopCalled);
}
```

JavaScript client code: accessing `lastError` in the `disconnect` event.

```
$.connection.hub.disconnected(function () {
    if ($.connection.hub.lastError)
        { alert("Disconnected. Reason: " +  $.connection.hub.lastError.message); }
});
```

Working with Groups in SignalR

2/20/2020 • 8 minutes to read • Edit Online

by Patrick Fletcher, Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This topic describes how to add users to groups and persist group membership information.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Overview

Groups in SignalR provide a method for broadcasting messages to specified subsets of connected clients. A group can have any number of clients, and a client can be a member of any number of groups. You don't have to explicitly create groups. In effect, a group is automatically created the first time you specify its name in a call to Groups.Add, and it is deleted when you remove the last connection from membership in it. For an introduction to using groups, see How to manage group membership from the Hub class in the Hubs API - Server Guide.

There is no API for getting a group membership list or a list of groups. SignalR sends messages to clients and groups based on a pub/sub model, and the server does not maintain lists of groups or group memberships. This helps maximize scalability, because whenever you add a node to a web farm, any state that SignalR maintains has to be propagated to the new node.

When you add a user to a group using the `Groups.Add` method, the user receives messages directed to that group for the duration of the current connection, but the user's membership in that group is not persisted beyond the current connection. If you want to permanently retain information about groups and group membership, you must store that data in a repository such as a database or Azure table storage. Then, each time a user connects to your application, you retrieve from the repository which groups the user belongs to, and manually add that user to those groups.

When reconnecting after a temporary disruption, the user automatically re-joins the previously-assigned groups. Automatically rejoining a group only applies when reconnecting, not when establishing a new connection. A digitally-signed token is passed from the client that contains the list of previously-assigned groups. If you want to

verify whether the user belongs to the requested groups, you can override the default behavior.

This topic includes the following sections:

- Adding and removing users
- Calling members of a group
- Storing group membership in a database
- Storing group membership in Azure table storage
- Verifying group membership when reconnecting

Adding and removing users

To add or remove users from a group, you call the Add or Remove methods, and pass in the user's connection id and group's name as parameters. You do not need to manually remove a user from a group when the connection ends.

The following example shows the `Groups.Add` and `Groups.Remove` methods used in Hub methods.

```
public class ContosoChatHub : Hub
{
    public Task JoinRoom(string roomName)
    {
        return Groups.Add(Context.ConnectionId, roomName);
    }

    public Task LeaveRoom(string roomName)
    {
        return Groups.Remove(Context.ConnectionId, roomName);
    }
}
```

The `Groups.Add` and `Groups.Remove` methods execute asynchronously.

If you want to add a client to a group and immediately send a message to the client by using the group, you have to make sure that the Groups.Add method finishes first. The following code examples show how to do that.

```
public async Task JoinRoom(string roomName)
{
    await Groups.Add(Context.ConnectionId, roomName);
    Clients.Group(roomName).addChatMessage(Context.User.Identity.Name + " joined.");
}
```

In general, you should not include `await` when calling the `Groups.Remove` method because the connection id that you are trying to remove might no longer be available. In that case, `TaskCanceledException` is thrown after the request times out. If your application must ensure that the user has been removed from the group before sending a message to the group, you can add `await` before `Groups.Remove`, and then catch the `TaskCanceledException` exception that might be thrown.

Calling members of a group

You can send messages to all of the members of a group or only specified members of the group, as shown in the following examples.

- **All** connected clients in a specified group.

  ```
  Clients.Group(groupName).addChatMessage(name, message);
  ```

- All connected clients in a specified group **except the specified clients**, identified by connection ID.

```
Clients.Group(groupName, connectionId1, connectionId2).addChatMessage(name, message);
```

- All connected clients in a specified group **except the calling client**.

```
Clients.OthersInGroup(groupName).addChatMessage(name, message);
```

Storing group membership in a database

The following examples show how to retain group and user information in a database. You can use any data access technology; however, the example below shows how to define models using Entity Framework. These entity models correspond to database tables and fields. Your data structure could vary considerably depending on the requirements of your application. This example includes a class named `ConversationRoom` which would be unique to an application that enables users to join conversations about different subjects, such as sports or gardening. This example also includes a class for the connections. The connection class is not absolutely required for tracking group membership but is frequently part of robust solution to tracking users.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.Data.Entity;

namespace GroupsExample
{
    public class UserContext : DbContext
    {
        public DbSet<User> Users { get; set; }
        public DbSet<Connection> Connections { get; set; }
        public DbSet<ConversationRoom> Rooms { get; set; }
    }

    public class User
    {
        [Key]
        public string UserName { get; set; }
        public ICollection<Connection> Connections { get; set; }
        public virtual ICollection<ConversationRoom> Rooms { get; set; }
    }

    public class Connection
    {
        public string ConnectionID { get; set; }
        public string UserAgent { get; set; }
        public bool Connected { get; set; }
    }

    public class ConversationRoom
    {
        [Key]
        public string RoomName { get; set; }
        public virtual ICollection<User> Users { get; set; }
    }
}
```

Then, in the hub, you can retrieve the group and user information from the database and manually add the user to the appropriate groups. The example does not include code for tracking the user connections. In this example, the `await` keyword is not applied before `Groups.Add` because a message is not immediately sent to members of the group. If you want to send a message to all members of the group immediately after adding the new member,

you would want to apply the `await` keyword to make sure the asynchronous operation has completed.

```
using Microsoft.AspNet.SignalR;
using System;
using System.Collections.Generic;
using System.Data.Entity;
using System.Linq;
using System.Threading.Tasks;

namespace GroupsExample
{
    [Authorize]
    public class ChatHub : Hub
    {
        public override Task OnConnected()
        {
            using (var db = new UserContext())
            {
                // Retrieve user.
                var user = db.Users
                    .Include(u => u.Rooms)
                    .SingleOrDefault(u => u.UserName == Context.User.Identity.Name);

                // If user does not exist in database, must add.
                if (user == null)
                {
                    user = new User()
                    {
                        UserName = Context.User.Identity.Name
                    };
                    db.Users.Add(user);
                    db.SaveChanges();
                }
                else
                {
                    // Add to each assigned group.
                    foreach (var item in user.Rooms)
                    {
                        Groups.Add(Context.ConnectionId, item.RoomName);
                    }
                }
            }
            return base.OnConnected();
        }

        public void AddToRoom(string roomName)
        {
            using (var db = new UserContext())
            {
                // Retrieve room.
                var room = db.Rooms.Find(roomName);

                if (room != null)
                {
                    var user = new User() { UserName = Context.User.Identity.Name};
                    db.Users.Attach(user);

                    room.Users.Add(user);
                    db.SaveChanges();
                    Groups.Add(Context.ConnectionId, roomName);
                }
            }
        }

        public void RemoveFromRoom(string roomName)
        {
            using (var db = new UserContext())
            {
```

```
                // Retrieve room.
                var room = db.Rooms.Find(roomName);
                if (room != null)
                {
                    var user = new User() { UserName = Context.User.Identity.Name };
                    db.Users.Attach(user);

                    room.Users.Remove(user);
                    db.SaveChanges();

                    Groups.Remove(Context.ConnectionId, roomName);
                }
            }
        }
    }
}
```

Storing group membership in Azure table storage

Using Azure table storage to store group and user information is similar to using a database. The following example shows a table entity that stores the user name and group name.

```
using Microsoft.WindowsAzure.Storage.Table;
using System;

namespace GroupsExample
{
    public class UserGroupEntity : TableEntity
    {
        public UserGroupEntity() { }

        public UserGroupEntity(string userName, string groupName)
        {
            this.PartitionKey = userName;
            this.RowKey = groupName;
        }
    }
}
```

In the hub, you retrieve the assigned groups when the user connects.

```
using Microsoft.AspNet.SignalR;
using System;
using System.Collections.Generic;
using System.Threading.Tasks;
using Microsoft.WindowsAzure.Storage.Table;
using Microsoft.WindowsAzure.Storage;
using Microsoft.WindowsAzure;

namespace GroupsExample
{
    [Authorize]
    public class ChatHub : Hub
    {
        public override Task OnConnected()
        {
            string userName = Context.User.Identity.Name;

            var table = GetRoomTable();
            table.CreateIfNotExists();
            var query = new TableQuery<UserGroupEntity>()
                .Where(TableQuery.GenerateFilterCondition(
                "PartitionKey", QueryComparisons.Equal, userName));
```

```
            foreach (var entity in table.ExecuteQuery(query))
            {
                Groups.Add(Context.ConnectionId, entity.RowKey);
            }

            return base.OnConnected();
        }

        public Task AddToRoom(string roomName)
        {
            string userName = Context.User.Identity.Name;

            var table = GetRoomTable();

            var insertOperation = TableOperation.InsertOrReplace(
                new UserGroupEntity(userName, roomName));
            table.Execute(insertOperation);

            return Groups.Add(Context.ConnectionId, roomName);
        }

        public Task RemoveFromRoom(string roomName)
        {
            string userName = Context.User.Identity.Name;

            var table = GetRoomTable();

            var retrieveOperation = TableOperation.Retrieve<UserGroupEntity>(
                userName, roomName);
            var retrievedResult = table.Execute(retrieveOperation);

            var deleteEntity = (UserGroupEntity)retrievedResult.Result;

            if (deleteEntity != null)
            {
                var deleteOperation = TableOperation.Delete(deleteEntity);
                table.Execute(deleteOperation);
            }

            return Groups.Remove(Context.ConnectionId, roomName);
        }

       private CloudTable GetRoomTable()
        {
            var storageAccount =
                CloudStorageAccount.Parse(
                CloudConfigurationManager.GetSetting("StorageConnectionString"));
            var tableClient = storageAccount.CreateCloudTableClient();
            return tableClient.GetTableReference("room");
        }
    }
}
```

Verifying group membership when reconnecting

By default, SignalR automatically re-assigns a user to the appropriate groups when reconnecting from a temporary disruption, such as when a connection is dropped and re-established before the connection times out. The user's group information is passed in a token when reconnecting, and that token is verified on the server. For information about the verification process for rejoining users to groups, see Rejoining groups when reconnecting.

In general, you should use the default behavior of automatically rejoining groups on reconnect. SignalR groups are not intended as a security mechanism for restricting access to sensitive data. However, if your application must double-check a user's group membership when reconnecting, you can override the default behavior. Changing the default behavior can add a burden to your database because a user's group membership must be

retrieved for each reconnection rather than just when the user connects.

If you must verify group membership on reconnect, create a new hub pipeline module that returns a list of assigned groups, as shown below.

```
using Microsoft.AspNet.SignalR;
using Microsoft.AspNet.SignalR.Hubs;
using System;
using System.Collections.Generic;
using System.Data.Entity;
using System.Linq;

namespace GroupsExample
{
    public class RejoingGroupPipelineModule : HubPipelineModule
    {
        public override Func<HubDescriptor, IRequest, IList<string>, IList<string>>
            BuildRejoiningGroups(Func<HubDescriptor, IRequest, IList<string>, IList<string>>
            rejoiningGroups)
        {
            rejoiningGroups = (hb, r, l) =>
            {
                List<string> assignedRooms = new List<string>();
                using (var db = new UserContext())
                {
                    var user = db.Users.Include(u => u.Rooms)
                        .Single(u => u.UserName == r.User.Identity.Name);
                    foreach (var item in user.Rooms)
                    {
                        assignedRooms.Add(item.RoomName);
                    }
                }
                return assignedRooms;
            };

            return rejoiningGroups;
        }
    }
}
```

Then, add that module to the hub pipeline, as highlighted below.

```
public partial class Startup {
    public void Configuration(IAppBuilder app) {
        app.MapSignalR();
        GlobalHost.HubPipeline.AddModule(new RejoingGroupPipelineModule());
    }
}
```

Mapping SignalR Users to Connections

2/20/2020 • 8 minutes to read • Edit Online

by Tom FitzMacken

WARNING

This documentation isn't for the latest version of SignalR. Take a look at ASP.NET Core SignalR.

This topic shows how to retain information about users and their connections.

Patrick Fletcher helped write this topic.

Software versions used in this topic

- Visual Studio 2013
- .NET 4.5
- SignalR version 2

Previous versions of this topic

For information about earlier versions of SignalR, see SignalR Older Versions.

Questions and comments

Please leave feedback on how you liked this tutorial and what we could improve in the comments at the bottom of the page. If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET SignalR forum or StackOverflow.com.

Introduction

Each client connecting to a hub passes a unique connection id. You can retrieve this value in the `Context.ConnectionId` property of the hub context. If your application needs to map a user to the connection id and persist that mapping, you can use one of the following:

- The User ID Provider (SignalR 2)
- In-memory storage, such as a dictionary
- SignalR group for each user
- Permanent, external storage, such as a database table or Azure table storage

Each of these implementations is shown in this topic. You use the `OnConnected`, `OnDisconnected`, and `OnReconnected` methods of the `Hub` class to track the user connection status.

The best approach for your application depends on:

- The number of web servers hosting your application.
- Whether you need to get a list of the currently connected users.
- Whether you need to persist group and user information when the application or server restarts.
- Whether the latency of calling an external server is an issue.

The following table shows which approach works for these considerations.

	MORE THAN ONE SERVER	GET LIST OF CURRENTLY CONNECTED USERS	PERSIST INFORMATION AFTER RESTARTS	OPTIMAL PERFORMANCE
UserID Provider	✓			✓
In-memory		✓		✓
Single-user groups	✓			✓
Permanent, external	✓	✓	✓	

IUserID provider

This feature allows users to specify what the userId is based on an IRequest via a new interface IUserIdProvider.

The IUserIdProvider

```
public interface IUserIdProvider
{
    string GetUserId(IRequest request);
}
```

By default, there will be an implementation that uses the user's `IPrincipal.Identity.Name` as the user name. To change this, register your implementation of `IUserIdProvider` with the global host when your application starts:

```
GlobalHost.DependencyResolver.Register(typeof(IUserIdProvider), () => new MyIdProvider());
```

From within a hub, you'll be able to send messages to these users via the following API:

Sending a message to a specific user

```
public class MyHub : Hub
{
    public void Send(string userId, string message)
    {
        Clients.User(userId).send(message);
    }
}
```

In-memory storage

The following examples show how to retain connection and user information in a dictionary that is stored in memory. The dictionary uses a `HashSet` to store the connection id. At any time a user could have more than one connection to the SignalR application. For example, a user who is connected through multiple devices or more than one browser tab would have more than one connection id.

If the application shuts down, all of the information is lost, but it will be re-populated as the users re-establish their connections. In-memory storage does not work if your environment includes more than one web server because each server would have a separate collection of connections.

The first example shows a class that manages the mapping of users to connections. The key for the HashSet will be the user's name.

```
using System.Collections.Generic;
using System.Linq;

namespace BasicChat
{
    public class ConnectionMapping<T>
    {
        private readonly Dictionary<T, HashSet<string>> _connections =
            new Dictionary<T, HashSet<string>>();

        public int Count
        {
            get
            {
                return _connections.Count;
            }
        }

        public void Add(T key, string connectionId)
        {
            lock (_connections)
            {
                HashSet<string> connections;
                if (!_connections.TryGetValue(key, out connections))
                {
                    connections = new HashSet<string>();
                    _connections.Add(key, connections);
                }

                lock (connections)
                {
                    connections.Add(connectionId);
                }
            }
        }

        public IEnumerable<string> GetConnections(T key)
        {
            HashSet<string> connections;
            if (_connections.TryGetValue(key, out connections))
            {
                return connections;
            }

            return Enumerable.Empty<string>();
        }

        public void Remove(T key, string connectionId)
        {
            lock (_connections)
            {
                HashSet<string> connections;
                if (!_connections.TryGetValue(key, out connections))
                {
                    return;
                }

                lock (connections)
                {
                    connections.Remove(connectionId);

                    if (connections.Count == 0)
                    {
                        _connections.Remove(key);
                    }
                }
            }
        }
```

```
    }
}
```

The next example shows how to use the connection mapping class from a hub. The instance of the class is stored in a variable name `_connections`.

```
using System.Threading.Tasks;
using Microsoft.AspNet.SignalR;

namespace BasicChat
{
    [Authorize]
    public class ChatHub : Hub
    {
        private readonly static ConnectionMapping<string> _connections =
            new ConnectionMapping<string>();

        public void SendChatMessage(string who, string message)
        {
            string name = Context.User.Identity.Name;

            foreach (var connectionId in _connections.GetConnections(who))
            {
                Clients.Client(connectionId).addChatMessage(name + ": " + message);
            }
        }

        public override Task OnConnected()
        {
            string name = Context.User.Identity.Name;

            _connections.Add(name, Context.ConnectionId);

            return base.OnConnected();
        }

        public override Task OnDisconnected(bool stopCalled)
        {
            string name = Context.User.Identity.Name;

            _connections.Remove(name, Context.ConnectionId);

            return base.OnDisconnected(stopCalled);
        }

        public override Task OnReconnected()
        {
            string name = Context.User.Identity.Name;

            if (!_connections.GetConnections(name).Contains(Context.ConnectionId))
            {
                _connections.Add(name, Context.ConnectionId);
            }

            return base.OnReconnected();
        }
    }
}
```

Single-user groups

You can create a group for each user, and then send a message to that group when you want to reach only that user. The name of each group is the name of the user. If a user has more than one connection, each connection id is

added to the user's group.

You should not manually remove the user from the group when the user disconnects. This action is automatically performed by the SignalR framework.

The following example shows how to implement single-user groups.

```
using Microsoft.AspNet.SignalR;
using System;
using System.Threading.Tasks;

namespace BasicChat
{
    [Authorize]
    public class ChatHub : Hub
    {
        public void SendChatMessage(string who, string message)
        {
            string name = Context.User.Identity.Name;

            Clients.Group(who).addChatMessage(name + ": " + message);
        }

        public override Task OnConnected()
        {
            string name = Context.User.Identity.Name;

            Groups.Add(Context.ConnectionId, name);

            return base.OnConnected();
        }
    }
}
```

Permanent, external storage

This topic shows how to use either a database or Azure table storage for storing connection information. This approach works when you have multiple web servers because each web server can interact with the same data repository. If your web servers stop working or the application restarts, the `OnDisconnected` method is not called. Therefore, it is possible that your data repository will have records for connection ids that are no longer valid. To clean up these orphaned records, you may wish to invalidate any connection that was created outside of a timeframe that is relevant to your application. The examples in this section include a value for tracking when the connection was created, but do not show how to clean up old records because you may want to do that as background process.

Database

The following examples show how to retain connection and user information in a database. You can use any data access technology; however, the example below shows how to define models using Entity Framework. These entity models correspond to database tables and fields. Your data structure could vary considerably depending on the requirements of your application.

The first example shows how to define a user entity that can be associated with many connection entities.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.Data.Entity;

namespace MapUsersSample
{
    public class UserContext : DbContext
    {
        public DbSet<User> Users { get; set; }
        public DbSet<Connection> Connections { get; set; }
    }

    public class User
    {
        [Key]
        public string UserName { get; set; }
        public ICollection<Connection> Connections { get; set; }
    }

    public class Connection
    {
        public string ConnectionID { get; set; }
        public string UserAgent { get; set; }
        public bool Connected { get; set; }
    }
}
```

Then, from the hub, you can track the state of each connection with the code shown below.

```
using System;
using System.Data.Entity;
using System.Linq;
using System.Threading.Tasks;
using System.Collections.Concurrent;
using Microsoft.AspNet.SignalR;

namespace MapUsersSample
{
    [Authorize]
    public class ChatHub : Hub
    {
        public void SendChatMessage(string who, string message)
        {
            var name = Context.User.Identity.Name;
            using (var db = new UserContext())
            {
                var user = db.Users.Find(who);
                if (user == null)
                {
                    Clients.Caller.showErrorMessage("Could not find that user.");
                }
                else
                {
                    db.Entry(user)
                        .Collection(u => u.Connections)
                        .Query()
                        .Where(c => c.Connected == true)
                        .Load();

                    if (user.Connections == null)
                    {
                        Clients.Caller.showErrorMessage("The user is no longer connected.");
                    }
                    else
                    {
```

```
                        foreach (var connection in user.Connections)
                        {
                            Clients.Client(connection.ConnectionID)
                                .addChatMessage(name + ": " + message);
                        }
                    }
                }
            }
        }

        public override Task OnConnected()
        {
            var name = Context.User.Identity.Name;
            using (var db = new UserContext())
            {
                var user = db.Users
                    .Include(u => u.Connections)
                    .SingleOrDefault(u => u.UserName == name);

                if (user == null)
                {
                    user = new User
                    {
                        UserName = name,
                        Connections = new List<Connection>()
                    };
                    db.Users.Add(user);
                }

                user.Connections.Add(new Connection
                {
                    ConnectionID = Context.ConnectionId,
                    UserAgent = Context.Request.Headers["User-Agent"],
                    Connected = true
                });
